#### Abstract

When we look at images, certain salient structures often attract our immediate attention, without requiring a systematic scan of the entire image. In subsequent stages, processing resources can be allocated preferentially to these salient structures. In many cases this saliency is a property of the structure as a whole, i.e., parts of the structure are not salient in isolation.

In this paper we present a saliency measure based on curvature and curvature variation. The structures this measure emphasizes are also salient in human perception, and they often correspond to objects of interest in the image.

We present a method for computing the saliency by a simple iterative scheme, using a uniform network of locally connected processing elements. The network uses an optimization approach to produce a "saliency map", which is a representation of the image emphasizing salient locations. The main properties of the network are: (i) the computations are simple and local, (ii) globally salient structures emerge with a small number of iterations, (iii) as a by-product of the computation contours are smoothed, and gaps are filled-in.

### 1. Introduction

Salient structures can often be perceived in an image at a glance. They appear to attract our attention without the need to scan the entire image in a systematic manner, and without prior expectations regarding their shape. The processes involved in the perception of salient structures appear to play a useful role in segmentation and recognition, since they allow us to immediately concentrate on objects of interest in the image.

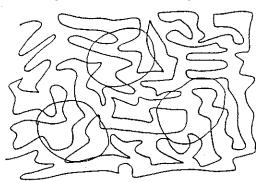

Figure 1. Three prominent blobs are perceived immediately and with little effort. Locally, the blobs are similar to the background contours (adopted from [5]). The blobs remain salient when intersections are added to the background curves [11].

Consider the images in figures 1, 2 and 3. Certain objects in each image somehow attract our attention in a manner often described as 'preattentive'. For instance, the large blobs in Fig. 1 are prominent, although locally the blobs' contours are indistinguishable from background contours on the basis of local orientation, curvature, contrast, etc. It seems as if one must somehow capture most of the curve bounding a blob in order to perceive it as a prominent structure. The circle in Fig. 2 is immediately perceived although its contour is fragmented, implying that gaps do not hinder the immediate perception of such objects. In this case one must group together several line segments of the circle to distinguish it from the background. These examples also demonstrate that these prominent objects need not be recognized in order for them to be distinguished. The image in Fig. 3 is an edge image of a car in a cluttered background. Our attention is drawn immediately to the region of interest in the image. It seems that the car need not be recognized to attract our attention. When the image is inverted and presented for short periods, recognition becomes considerably more difficult, yet the same region remains salient.

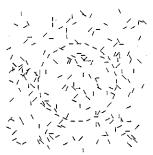

Figure 2. A circle in a background of 200 randomly placed and oriented segments. The circle is still perceived immediately although its contour is fragmented.

The goal of this paper is to suggest what makes structures such as those in Fig. 1-3 salient, and to propose a mechanism for detecting salient locations in an image. A locally connected network is proposed that can process images such as the figures above to construct a "saliency map", which is a representation of the image emphasizing salient locations. The computations of the net are devised to meet the following requirements: (i) the time it takes to detect a prominent structure does not depend on the complexity of background curves, (ii) curves may have any number of gaps, and (iii) the number of computations are restricted to the order of dozens or, at most, about a hundred steps in order to meet the time constraint involved in immediate perception.

Figure 3. An edge image of a car in a cluttered background. Our attention is drawn immediately to the region of interest. It seems that the car need not be recognized to attract our attention. The car also remains salient when parallel lines and small blobs are removed, and when the less textured region surrounding parts of the car is filled in with more texture.

Issues related to this problem include segmentation, perceptual organization, and figure/ground separation. Segmentation schemes have been investigated extensively in the field of computer vision and many algorithms have been suggested. They will not be reviewed here, since they are only marginally related to the problem at hand. Many of the segmentation processes that have been proposed were more ambitious than what is required, or what is possible, to achieve in the early stages where prominent areas are located. For example, they attempt to segment the entire image instead of just an area of interest. Our proposal is related to the suggestion made by Ullman [14] that segmentation should be conducted on an area of interest rather than applied to the entire image, implying that some preattantive process is required to detect prominent locations from which an area of interest is defined, prior to the act of segmentation.

Lowe's [4] treatment of perceptual organization is more closely related to the problem addressed in this paper. The processes proposed by Lowe detect instances of collinearity, cotermination and parallelism among straight lines, and will not be effective in cases (e.g. Fig. 1) where these conditions do not play a major role. Most past approaches for segmentation also do not meet the requirements set above. In particular, they do not meet the time constraint and they depend critically on the complexity of the background curves.

#### 1.1 Local and Global Saliency

The phenomena related to the perception of salient structures can be roughly divided into two classes. The first, referred to as local saliency, occurs when an element becomes conspicuous by having a simple distinguishing local property such as color, contrast, orientation, etc. For example, a red item placed among green ones immediately attracts attention by virtue of its unique color [2], [12]. The second case, referred to as structural saliency, occurs when the structure is perceived in a more global manner. That is, the local elements of the structure are not salient as in the former case but instead the arrangement of the elements is what makes the structure unique and salient.

We focus below on the saliency of curves, based on properties measured along them (the curves may be continuous or with any number of gaps). Not all phenomena of global immediate perception are necessarily accounted for by measuring properties of curves. For instance, one could measure the compactness of a structure, the degree of symmetry it contains and

other measures that are region-based rather than curve-based. Nevertheless, properties of curves are often sufficient in order to separate objects from their background.

The fact that structural saliency requires measures that have a global extent introduces a severe complexity problem. The number of possible groupings of local line segments into curves, where the curves are allowed to have any number of gaps, explodes exponentially. The complexity issue becomes acute when considering the fact that a salient curve of a given length is not necessarily composed of salient sub-parts. Thus, contemporary pyramid techniques (see [9] for a review) would not be appropriate for detecting structural saliency, because they contain an implicit assumption that a salient curve is composed of salient sub-parts.

### 2. Saliency as an Optimization Problem

Our goal is to construct a saliency map which is a representation of the image emphasizing salient locations. We seek to associate, therefore, a measure of saliency denoted by the function  $\Phi(\cdot)$  to each location in the image. A property that seems to play a role in structural saliency is the combination of length and smoothness measured at a particular scale. That is, a measure of saliency that would account for the type of images above is one that favors long smooth curves, where the smoothness of a curve is related to its curvature or its curvature variation. We therefore face the following problems:

- Defining an appropriate measure Φ that, when applied to a point along a given curve, will increase when the curve increases in length and smoothness.
- (2) A selection problem. The measure  $\Phi(P)$  depends on the curve passing through P. Since the curves we are considering are either continuous or separated by any number of gaps, there will usually be many possible curves to consider. Our approach to this problem will be to select the curve that maximizes  $\Phi(P)$  over all curves passing through P.

We defer the exact formulation of  $\Phi$  until we have examined the manner by which it is computed. The reason is that the general method of computing  $\Phi$  (using a simple local network) places strong constraints on the possible definition of  $\Phi$ . In the next sections we describe the mechanism by which  $\Phi$  is computed, and then derive an explicit formula for  $\Phi$ .

### 2.1 The Basic Elements

We assume that  $\Phi$  is computed by a locally connected network of processing elements. Our specific model is that at the level of computing saliency the image is represented by a network of  $n \times n$  grid points, where each point represents a specific x, y location in the image. At each point P there are k orientation elements coming into P from neighboring points, and the same number of orientation elements leaving P to nearby points. Each orientation element p, responds to an input image by signalling the presence of the corresponding line segment in the image, so that those elements that do not have an underlying line segment are associated with an empty area or gap in the image. We refer to a connected sequence of orientation elements  $p_i, ..., p_{i+N}$ , each element representing a line-segment or a gap, as a curve of length N (note that curves may be continuous or with any number of gaps). The optimization problem is formulated as maximizing  $\Phi_N$  over all curves of length N starting

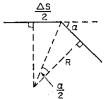

Figure 4. A discrete approximation to the curvature. R approximates the radius of curvature,  $\alpha$  is the orientation difference,  $\Delta s$  is the length of both elements.

where

$$f_{k,k+1} = e^{-\frac{2\alpha_k \tan \frac{m_k}{2}}{\Delta^2}} \tag{2.5}$$

 $C_{i,j}$  plays the role of a weight given to each local saliency value  $\sigma_j$  along the curve. A measure that gives a high score to long curves with low total curvature is now defined as:

$$\sum_{j=i}^{i+N} C_{i,j} \rho_{i,j} \sigma_j \tag{2.6}$$

The measure in (2.6) is a weighted contribution of the local saliency values  $\sigma_j$  along the curve. Each weight is a product of two factors. The first factor is inversely related to the number of virtual elements along  $p_i, ..., p_j$ , and the second factor is inversely related to the total curvature of the curve. Curves that will receive a high measure on (2.6) are long curves that are as straight as possible and have the least number of gaps. The measure in (2.6) is also extensible according to the definition in (2.1). This can be shown by induction on the length of the curve, and the proof will not be detailed here.

Other functions for measuring the optimality of curves, using multistage optimization, were suggested by [1], [6], [7]. The optimal curve in these cases is one that maximizes the sum of gray levels or edge magnitude along the curve, while minimizing the sum of orientation difference. In our terminology, the optimization function is:

$$\sum_{j=i}^{i+N} \sigma_j - \sum_{j=i}^{i+N} \alpha_j$$

This measure, however, is insensitive to the distribution of orientation difference along the curve and in general does not satisfy the requirement to prefer long and as-straight-as-possible curves.

## 3. The Saliency Network

In this section we summarize the computation performed by the network and its relation to the saliency measure defined above. The orientation elements constitute the basic computing elements of the net. Each element  $p_i$  is associated with a processor that can perform some computation based on its state and the state of its k neighboring processors. This defines a uniform network containing  $kn^2$  processing units, with local communication. In the current implementation k is equal to 16, providing a reasonable angular resolution.

## 3.1 Computation of Elements in the Network

Each element  $p_i$  is associated with a state variable denoted by  $E_i$  and a set of three attributes that includes its local saliency

 $\sigma_i$ , its orientation  $\theta_i$  and its attenuation factor  $\rho_i$ . Each element  $p_i$  updates its state variable  $E_i$  iteratively through a local computation. At the end of iteration N,  $E_i$  contains the measure of saliency derived in (2.6) which will be maximal over all possible curves of length N starting at  $p_i$ , where these curves are either continuous or with any number of gaps.

 $E_i$  is updated by the following computation:

$$E_{i}^{(0)} = \sigma_{i}$$

$$E_{i}^{(n+1)} = \sigma_{i} + \rho_{i} \max_{p_{j} \in \delta(p_{i})} E_{j}^{(n)} f_{i,j}$$
(3.1)

where  $p_j$  is one of k possible neighbors of  $p_i$ , and  $f_{i,j}$  are the "coupling constants" defined in (2.5). To unravel the recurrence formula above, we isolate a specified curve  $\gamma$  represented by  $\theta_i, ..., \theta_{i+N}$  where each element along the curve has only a single neighboring element to communicate with. The following proposition relates the value of the state variable of  $p_i$  with the measure in (2.6).

Proposition 1:

$$E_i^{(N)} = \sum_{j=i}^{i+N} C_{i,j} \rho_{i,j} \sigma_j$$

The proof is by induction on the length of the curve and will not be detailed here. The proposition above together with that the measure is extensible implies that among all possible curves  $\gamma_i$  of length N starting from  $p_i$ , either continuous or with any number of gaps,  $E_i$  will be computed along that curve which is maximal with respect to the measure in (2.6), namely

$$E_i^{(N)} = \max_{\gamma_i} \sum_j C_{i,j} \rho_{i,j} \sigma_j$$

taken over all  $\gamma_i$ . It is worth noting that the fact that the measure  $\Phi$  is extensible, does not imply that the optimal contour through P simply extends itself as the iterations proceed. In fact, the optimal curve at stage N+1 can be different from the optimal curve at stage N. Furthermore, note that the saliency value is defined for an element  $p_i$  by measuring the saliency of the 'best' curve of length N starting from  $p_i$ . Hence, two elements on the same curve may have different saliency values because both curves, starting from both elements respectively, do not necessarily have the same properties with respect to (2.6).

The state values of elements in the network form a new representation of the image which is a 'biased' view of the visual environment, emphasizing interesting or conspicuous locations. We denote this representation as the saliency map. The term of saliency map was used by [3] for representing (using our terms) local saliency.

## 3.2 Additional Properties of the Network

Convergence Property. The concept of an iterative computation raises the issue of convergence when the number of iterations goes to infinity. This issue is important in the context of the saliency network because an element  $p_i$  might be influenced by its own state in a feedback loop if it lies on a closed curve. The following proposition considers a closed curve and evaluates the state of an element of the curve after an infinite number of iterations.

proposition 2:

Consider  $p_i, ..., p_{i+N}$  a closed curve where  $p_i = p_{i+N+1}$ . The

from  $p_i$ :

$$\max_{(p_{i+1},...,p_{i+N})\in\delta^N(p_i)}\Phi_N(p_i,...,p_{i+N})$$

where  $\delta^N(p_i)$  is the set of all possible curves of length N starting from  $p_i$ .

A naive approach to this problem would involve an exhaustive enumeration of all combinations of  $p_{i+1}, ..., p_{i+N}$  which would require an exponential search space of size  $k^N$  for each element in the network. In what follows, we will show that for a certain class of measures  $\Phi$  ("extensible" measures), the computation becomes linear in N. We will then define a saliency measure  $\Phi$  that measures length and smoothness, and at the same time is extensible and can be computed efficiently.

# 2.2 Multistage Optimization Approach

For a certain class of measures  $\Phi(\cdot)$ , the computation of  $\Phi_N$  can be obtained by iterating a simple local computation. To illustrate, let us consider first curves that are only three elements long. The problem in this case is:

$$\max_{(p_{i+1}, p_{i+2}) \in \delta^2(p_i)} \Phi_2(p_i, p_{i+1}, p_{i+2})$$

That is, for a given element  $p_i$ , determine  $p_{i+1}$  (one of  $p_i$ 's k neighbors) and  $p_{i+2}$  (a neighbor of  $p_{i+1}$ ) such that  $\Phi_2(p_i, p_{i+1}, p_{i+2})$  will be maximal. A naive approach will again require examining the  $k^2$  different curves. Assume, however, that  $\Phi_2$  satisfies the condition:

$$\max_{\delta^{2}(p_{i})} \Phi_{2}(p_{i}, p_{i+1}, p_{i+2}) = \max_{p_{i+1}} \Phi_{1}(p_{i}, \max_{p_{i+2}} \Phi_{1}(p_{i+1}, p_{i+2}))$$

In this case maximizing  $\Phi_2$  can be achieved by repeating the application of  $\Phi_1$  over shorter curves. The general approach is formulated in a similar manner:

$$\max_{\delta^{N}(p_{i})} \Phi_{N}(p_{i},...,p_{i+N}) = \max_{\beta^{N}(p_{i})} \Phi_{1}(p_{i},\max_{\delta^{N-1}(p_{i+1})} \Phi_{N-1}(p_{i+1},...,p_{i+N})) \quad (2.1)$$

where  $\delta(p_i)$  stands for  $\delta^1(p_i)$ . In this manner we reduce the search space needed for each curve of length N starting from  $p_i$  to the size of kN instead of  $k^N$  that is needed for the naive approach. The principle in (2.1) is related to the principle of optimality underlying all multistage decision processes, and in particular it is a special case of Dynamic Programming. We refer to the family of functions that obey the principle in (2.1) as extensible functions. We next derive an extensible function that prefers long curves that have low total curvature.

#### 2.3 Deriving the Saliency Measure

Two factors play a role in the measure of saliency. The first factor is related to the length of the curve, and the second factor is related to its shape. The length of a curve is related to the number of elements on the curve that have an actual curve (rather than a gap) passing through them. These elements are referred to as active elements, whereas the elements that are associated with gaps are referred to as virtual elements. To each element, then  $\sigma_i$  is set to be a positive value, which for the present is set to 1, and for a virtual element  $\sigma_i$  is set to 0. The measure related to the length of the curve  $p_i, ..., p_{i+N}$  is:

$$\sum_{j=i}^{i+N} \sigma_j \tag{2.2}$$

The measure above is a sum of the local saliency values of the active elements along the curve.  $\sum \sigma_j$  is in the range of 0 to N+1 depending on the number of active elements, implying that a continuous curve scores higher than a fragmented one of the same length. It is also possible to 'penalize' the existence of gaps, especially large ones, in order to attenuate the measure given to the curve when it is too fragmented. Penalizing the existence of gaps is obtained by associating an attenuation factor  $\rho_i$  to each element  $p_i$ . If  $p_i$  is active then  $\rho_i$  is set to a value smaller or equal 1 (for the present it is set to 1). If  $p_i$  is virtual, then  $\rho_i = \rho < 1$ . We define an attenuation function associated with the curve  $p_i, ..., p_j$  as follows:

$$\rho_{i,j} = \prod_{k=i+1}^{j} \rho_k$$

where  $\rho_{i,i} = 1$ . The measure in (2.2) is modified by the attenuation factors:

$$\sum_{j=i}^{i+N} \rho_{i,j} \sigma_j \tag{2.3}$$

The measure in (2.3) is a weighted contribution of the local saliency values  $\sigma_j$  along the curve, where the weights are inversely related to the number of virtual elements along  $p_i, ..., p_j$ . The role of attenuation factors is emphasized in light of the network's computation (presented in the sequel) which enables curves to extend themselves across gaps. In practice we would like to place a bound on the size of gaps that can be completed so that remote disconnected curves would not be considered as part of one fragmented curve. The measure in (2.3) essentially achieves this goal.

In order to measure the shape of the curve we use a measure that is inversely related to the total curvature of the curve. The total curvature of a curve  $\gamma$  is defined as  $\int_{\gamma} \left(\frac{d\theta}{ds}\right)^2 ds$ , where  $\theta(s)$  is the slope along the curve, and  $\frac{d\theta}{ds}$  at point P is known as the local curvature at that point (the inverse of R, the radius of curvature). We would like to use the total curvature to obtain a measure that is bounded, and is inversely related to the total curvature. The following measure meets these requirements:

$$e^{-\int_{\gamma} \left(\frac{d\theta}{ds}\right)^2 ds} \tag{2.4}$$

which is confined to values between 0 and 1. A straight line receives the value 1, and a meandering curve will approach the limit 0 as its total curvature grows to infinity. To obtain a discrete approximation to the measure in (2.4) we denote by  $\alpha_k$  the orientation difference between the k'th element and its successor, and by  $\Delta s$  the length of an orientation element. The local curvature  $\frac{1}{R}$  to the curve tangent to these elements (see Fig. 4) is:

$$\frac{2\tan\frac{\alpha_k}{2}}{\Delta s}$$

The arc's length is  $\alpha_k R$ , and therefore the total curvature square is approximated by:

$$\frac{2\alpha_k\tan\frac{\alpha_k}{2}}{\Delta s}$$

The discrete approximation to the total curvature measure along  $p_i, ... p_j$  is therefore obtained by:

$$C_{i,j} = \prod_{k=i}^{j-1} f_{k,k+1}$$

state of  $p_i$  converges to the following value:

$$E_i^{(kN)} \longrightarrow_{k \to \infty} \frac{E_i^{(N)}}{1 - C_{i,i+N}\rho_{i,i+N}}$$

The proof is by induction on the length of the curve. The main point to notice is that a closed curve (even if it is fragmented) will increase its value when the number of iterations exceeds the curve's perimeter. If we consider a continuous circle of radius r, for example, then  $C_{i,i+N} = e^{-\frac{2\pi}{r}}$  which is always less than 1. In practice, the increase is considerably smaller than the limiting value because we perform a restricted number of iterations.

Curve Following. The computation performed by each element include a local preference between neighboring elements. That is, at each iteration each element  $p_i$  selects the neighbor  $p_j$  that contributes the most to its state. The information regarding local preference can be used to trace a linked curve starting from  $p_i$  in a recursive manner, namely,  $p_j$  is the second element in the curve,  $p_j$ 's preferred neighbor is the third element, etc. Given a conspicuous element as a starting point, we could extract the curve that is optimal according to (2.6). Examples of these curves are given in section 4.

Filling Gaps. The ability to cope with gaps is important for the applicability of the saliency network to real images. Edge maps obtained from real images are often corrupted by multiple gaps, and what seems as a smooth salient curve often turns out to be fragmented after edge detection has been applied.

A virtual element (that lies in a gap) participates in the computation of (3.1) in a similar manner to active elements. Consider for instance a gap starting from  $p_{j+1}$  and ending at  $p_{j+k}$ . That is,  $p_j$  is an active element, but  $p_{j+1},...,p_{j+k}$  are virtual elements. An element will update its state provided that it has at least one neighbor with a state value different from 0. It will take at most k iterations for  $p_{j+k}$  to update its state. The network will fill-in a curve  $\gamma_i$  that will maximize the value of  $ho^{|\gamma_i|}C_{j,j+k}$ . That is, the preference is for filled-in curves having low total curvature  $C_{j,j+k}$ , while minimizing their overall length  $|\gamma_i|$ . The relative weight of the two factors is controlled by setting the values of  $\rho$ . In the current implementation  $\rho$  was set to 0.7, which was found experimentally to give results that are generally in agreement with our own perception. The curves generated in this manner are similar (for orientation difference less than  $\frac{\pi}{2}$ ) to several other methods for completing gaps in contours and for modeling subjective contours in human perception [10], [13], [15].

## 3.3 Additional Computations of the Network

The Computation of Low Curvature Variation. The computation of the network summarized in (3.1) produce a saliency map based on the measure in (2.6). This does not rule out the possibility of additional properties that mediate structural saliency. For instance, the blobs in Fig. 1 seem to be prominent on the basis of low curvature variation rather than low overall curvature. A second saliency measure was therefore formulated that prefers long curves with low total curvature variation. Details of this second measure can be found in [11]. As a result, the saliency network constructs two saliency maps, one for each property, from which salient locations can be detected.

Smoothing the Measured Curves. The input to the saliency network is an edge map that determines which of the network's elements are active. The edges in the edge map are often noisy,

due to sensor noise, quantization effects, and various effects of the edge detection process. Reducing noise is important because what appears to be a smooth curve to our visual system may turn out to be rather serrated at the edge map level. Smoothing can be obtained in part by analyzing the same image at different resolutions. It turns out, however, that some smoothing is often desired within a given scale of analysis.

A naive approach would be to extract all curves, replace them by a smooth approximation and then apply the saliency network to the smoothed curves. However, such an approach will encounter the same complexity issue regarding the number of possible curves discussed in section 1.1. We handle the problem of smoothing curves as a local computation that is performed within the saliency network itself, as an integral part of computing the saliency measure. In a nutshell, the coordinates associated with each orientation element are modified in an iterative manner, to smooth the curve passing through that element. The approach underlying the computation is to associate an energy level to each curve so that the smooth approximation is of minimum energy. The energy functional is given by:

$$\frac{1}{2}\lambda \sum_{j=1}^{i+N} \left( (x_j - x_j^{(0)})^2 + (y_j - y_j^{(0)})^2 \right) \; + \; \frac{1}{2} \int_{\gamma} \left( \frac{d^2 \theta}{ds^2} \right)^2 \, ds$$

where  $(x_j, y_j)$  j = i, ..., i + N are the coordinates of the smooth approximation to the curve  $(x_j^0, y_j^0)$  j = i, ..., i + N. A curve of minimum energy is one that minimizes its total curvature variation while being as close as possible to the original curve. The parameter  $\lambda$  controls the relative weight between the two terms (for a similar energy functional see [8]). The energy is lowered at each iteration in a process that involves only local computations. These local computations are combined with those in (3.1), resulting a network which measures saliency of curves while smoothing them simultaneously. The details can be found in [11].

#### 4. Network Examples

The main issues illustrated by the examples are (i) the saliency map, and (ii) the by-product creation of linked curves, which is a by-product of the saliency computation.

Prominent locations in the image are represented as elements having a high measure of saliency as computed by the network. For illustration purposes the saliency map will be displayed as a gray-level image in which an element  $p_i$  is displayed as a bar of width  $\omega_i$  and intensity value  $\tau_i$ , which are set proportional to the state value  $E_i$ . In other words, increased saliency measure corresponds to an increase in brightness and in width of the element in the display. The most salient element is displayed as a white bar of width four, and the least salient element is displayed as a black segment.

The first example is a synthetic image (not produced by edge detection) shown in Fig. 2. It is constructed from a fragmented circle placed among a background of randomly placed and oriented elements. The number of background elements is 200 and the circle consists of 60 elements (active and virtual). The circle is immediately perceived by our visual system. The saliency network is applied to this image for ten iterations. Fig. 5 presents the saliency map after that period, and Fig. 6 presents the selected curve starting from the most salient element.

The result is in agreement with the perception of the circle by our visual system. The saliency measure of each element of the circle is significantly higher than the measure given to the

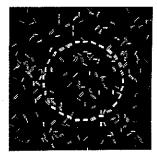

Figure 5. Saliency map of the image in Fig. 2 obtained by the network after 10 iterations. The saliency measure of each element of the circle is significantly higher than of the background elements.

Figure 6. The curve starting from the strongest element in figure 5. Virtual elements are displayed as dotted lines.

background elements. In this regard, the circle virtually 'popsout' from the saliency map.

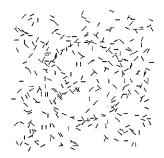

Figure 7. The same circle as in figure 2 but with 400 background segments.

The second point to notice is that a complete object is separated from the background although it is initially fragmented. This agrees with the observation that perception is not severely affected by the presence of gaps. The final point to notice is that although the length of the salient curve is 60 elements, the number of iterations required for distinguishing the circle from its background is considerably smaller. This happens because although each element of the circle is not salient by itself, groups of ten elements already become sufficiently salient. Outside the circle, the probability of having a low curvature chain of length ten is low.

In fact, the probability remains small even when the number

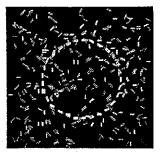

Figure 8. Saliency map of the image in Fig. 7 obtained by the network after 10 iterations.

of background elements increases considerably. To illustrate, we doubled the number of background elements as shown in Fig. 7. We applied again ten iterations to produce the saliency map in Fig. 8. Starting from the most salient element, the curve extracted by the network is identical with the one in Fig. 6.

The next example is the image in Fig. 3. Fig. 9 shows the saliency map after 30 iterations. Only the region surrounding the car is displayed. The saliency measure given to most of the elements of the car is significantly higher than that given to the background elements. Fig. 10 displays the five most salient curves obtained by tracing the most salient elements.

Note that the traced curves have been smoothed, and that the gaps have been filled in. The results suggest that the saliency computation is useful for distinguishing significant structures in

Figure 9. Saliency map of the image in Fig. 3 obtained by the network after 30 iterations. The region of interest virtually 'pops-out' from the display.

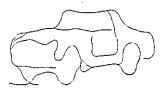

Figure 10. The five most salient curves obtained by tracing the most salient elements of figure 9. The curves have been smoothed and gaps have been filled in.

the image.

Figure 11. Saliency map for low curvature variation of the image in Fig. 1

The final example is the image in Fig. 1. The input to the network was obtained by edge detection from the original handdrawn image. We show the results for a part of the image containing one of the blobs. Fig. 11 displays the saliency map for low curvature variation after 160 iterations, which is twice the number of elements on the perimeter of the blob. The elements of the blob become stronger than the background elements after 70 iterations, in agreement with the observation that one must capture almost the entire blob in order to perceive it as prominent. Interestingly, the results of the low curvature map are similar, but about 100 iterations are required for the blob to become prominent. Fig. 12 displays the curve starting from the most salient element. In this case also the curve is smoothed by the network while measuring its saliency.

Figure 12. The curve starting from the strongest element in figure 11 is traced. The curve is smoothed by the network while measuring its saliency.

#### Summary

It is proposed that immediate perception includes processes for detecting salient structures in the image on which subsequent processes such as segmentation and recognition can focus. The saliency of a structure is divided into two sources, local saliency, and structural saliency. Of the two, structural saliency is more problematic from a computational point of view since it requires the efficient computation of certain global properties.

A locally connected network was devised to produce a saliency map, which is a representation of the image emphasizing salient locations. The network exhibits the following properties: (i) the computations are local and simple, (ii) the number of computations are in the order of dozens or up to about a hundred, (iii) there is little dependence on the complexity of the image, (iv) gaps in curves are filled in the course of the computation, (v) contours are smoothed in the course of producing a saliency map, (vi) the network produces linking information so that curve tracing across junctions, branches and gaps is possi-

ble, and (vii) the network is robust in the sense that malfunction of some processing units does not affect seriously the performance of the network.
