On the Complexity of
Verifying Concurrent Transition Systems

Abstract

In implementation verification, we check that an implementation is correct with respect to a specification by checking whether the behaviors of a transition system that models the program’s implementation correlate with the behaviors of a transition system that models its specification. In this paper, we investigate the effect of concurrency on the complexity of implementation verification. We consider trace-based and tree-based approaches to the verification of concurrent transition systems, with and without fairness. Our results show that in almost all cases the complexity of the problem is exponentially harder than that of the sequential case. Thus, as in the model-checking verification methodology, the state-explosion problem cannot be avoided.

1 Introduction

While program verification has always been desirable but never easy, the advent of concurrent programming has made it significantly more necessary and difficult. We distinguish between two main methodologies for formal verification. The first is temporal-logic model checking. Here, we verify the correctness of a program with respect to a desired behavior by checking whether a state-transition graph that models the program satisfies a temporal-logic formula that specifies constraints on its behavior. The second methodology is implementation verification. Here, we check that an implementation is correct with respect to a specification by checking whether the behaviors of a state-transition graph that models the program’s implementation correlate with the behaviors of a state-transition graph that models its specification.

The complexity of model checking is well known. For example, in the case of the temporal logics LTL and CTL, model checking can be carried out in space that is polynomial in \(n \log m\),

where \( n \) is the length of the formula and \( m \) is the size of the graph modeling the program [LP85, VW94, BVW94]. Keeping in mind that the formulas are usually small, it seems that model checking is easy and tractable. It suffers, however, acutely from the so-called state-explosion problem. In a concurrent setting, the program under consideration is typically the parallel composition of many processes, which implies that the size of the program graph is the product of the sizes of the graphs modeling the underlying processes. Accordingly, the model-checking problem for concurrent programs can be solved in space that is polynomial in \( nm \), where \( n \) is the length of the formula and \( m \) is the sum of the sizes of the graphs modeling the processes. Can we do better than this? Can we model-check a concurrent program and avoid the state-explosion problem? Unfortunately, the answer is no. Indeed, model checking of concurrent programs for LTL and CTL is PSPACE-complete even for a fixed formula [VW94, BVW94]. Hence, in the worst case we might need to traverse the exceedingly large state space introduced by the parallel composition. Coping with the state-explosion problem is one of the most important issues in computer-aided verification and is the subject of much active research (cf. [CGL93])

What about implementation verification? Is the state-explosion problem unavoidable there too? This is the subject of our work. We first describe implementation verification in more detail. Consider an implementation and a specification. Both describe possible behaviors of the program, but the implementation is more concrete than the specification, or, equivalently, the specification is more abstract than the implementation (cf. [AL91]). This basic notion suggests a top-down method for design development, called hierarchical refinement (cf. [LS84, Kur94]): Starting with a highly abstract specification, we construct a sequence of behavior descriptions, each of which refers to its predecessor as a specification, and is thus less abstract than the predecessor. At each stage the current implementation is verified to satisfy its specification. The last description in the sequence contains no abstractions, and constitutes the final implementation.

There are several ways of defining what it means for an implementation to satisfy a specification. The two main ones are trace-based and tree-based. The former requires each computation of the implementation to correlate with some computation of the specification, and the latter requires each computation tree embodied in the implementation to correlate with some computation tree embodied in the specification. The exact notion of correct implementation then depends on how we interpret correlation. Numerous proposals for this have been made and studied in the literature [Hen85, Mil89, AL91]. In this paper we adopt a simple interpretation, taking correlation to mean equivalence with respect to the variables joint to the implementation and the specification. One justification for this is the fact that the more concrete implementation is typically defined over a wider set of variables than the more abstract specification. With this interpretation, trace-based verification corresponds to establishing containment [Kur94] and tree-based verification corresponds to establishing simulation [Mil71].

We model concurrent programs (and hence implementations and specifications) by what we shall call concurrent transition systems. The basic motivation for this comes from the statecharts of [Har87], which can be viewed as finite automata with both concurrency and
hierarchy, though for simplicity we eliminate the hierarchy here. A concurrent transition system consists of components, which model the program’s underlying processes. (The analogous parts of a statechart are called orthogonal components in [Har87].) Each component is a state-transition graph. Its states correspond to the possible positions of the process it models, and each state is labeled with the events that occur, or hold, in the corresponding position. The transitions of the graph correspond to the possible steps of the process, with branches representing nondeterminism. To model the cooperation of processes during execution, the transitions are made conditional and can depend on the states of the other components. This approach to modeling concurrency, called bounded cooperative concurrency in [Har89, DH94], is the dominating one in research on distributed systems (cf. [Kur94]).

A concurrent transition system with a single component models a program with no concurrency, and we call it a sequential transition system. By [DH94], a concurrent transition system can be translated into a sequential transition system with an exponential blow up in size. Indeed, it is the size of this sequential system that is referred to in current analyses of the complexity of verification. The question we want to address here is whether the exponential blow up that hides in these analyses can be avoided if the program to be verified is concurrent.

Before we turn to this question, let us review some known results for the implementation verification of sequential transition systems (for full details, see Section 2.3). These results raise interesting issues concerning the relative merits of trace-based vs. tree-based verification. When we compare expressive power, for example, the tree-based approach is stronger, in the sense that while simulation implies containment, the opposite direction is not true [Mil80]. When we compare the two approaches from a complexity-theoretic point of view, the picture is controversial. We examine the complexity of the containment and the simulation problems in four different ways:

1. The joint complexity of containment and simulation. This measure considers the complexity in terms of both the implementation and the specification. The joint complexity of simulation is PTIME-complete [Mil80, BGS92], whereas that of containment is PSPACE-complete [SVW87].

2. The implementation complexity of containment and simulation. This measure considers the complexity in terms of the implementation, assuming the specification is fixed. Since the implementation is typically much larger than the specification, this measure is of particular interest. According to this measure, containment is easier than simulation [KV96].

3. The joint complexity of fair containment and fair simulation. When we consider fair transition systems [MP92], which enable the description of behaviors that satisfy both liveness and safety properties, containment and simulation are revised to consider only the fair computations of the implementation and the specification. The resulting problems, of fair containment and fair simulation [BBLS92, ASB+94, GL94] are both PSPACE-complete [KV96].
4. The implementation complexity of fair containment and fair simulation. Here, the advantage of the trace-based approach reappears [KV96].

We address the question about the power of concurrency in program verification by examining the four measures when applied to concurrent transition systems. We first define containment and simulation with respect to such systems, and then consider the complexity and the implementation complexity of detecting their presence. We then turn to defining fair-containment and fair-simulation with respect to concurrent transition systems, and study their complexities too, employing unconditional, weak, and strong fairness (also known as impartiality, justice, and compassion, respectively) [LPS81, MP92].

Before saying a little more about the results themselves, we clarify what we feel are the paper’s two main contributions. First, it continues the study of implementation verification in [Mil80, BGS92, KV96]. Unlike these papers, our complexity analysis addresses the state-explosion issue explicitly, by taking the size to be that of the concurrent systems themselves and not their sequential equivalents. In addition, our work continues the study of the power of bounded cooperative concurrency undertaken in [Har89, DH94, HH94, HRV90], the results in these papers show that cooperative concurrency exhibits inherent exponential power. The power criteria considered there are succinctness of finite automata and pushdown automata, and the effect of the succinctness gap on the difficulty of reasoning about transition systems on a propositional level. In the present paper, the power criteria is the complexity of the verification problem.

Our results strengthen the observations in [Har89, DH94, KV96]. Specifically, the question of whether the exponential nature of concurrency carries over to the verification problem is answered in the affirmative. We show that verifying concurrent transition systems is exponentially harder than verifying sequential transition systems, and thus the state-explosion problem cannot be avoided. This result is robust: It is independent of the verification approach and the fairness constraint under consideration, and remains valid when we consider implementation complexity too. In particular, we show that the fair-containment and fair-simulation problems for concurrent transition systems are EXPSPACE-complete. These results join those of [KV96] in questioning the computational superiority of tree-based verification.

One exception to the inherent exponential power of cooperative concurrency is the fair-simulation problem for strongly-fair transition systems. While the implementation complexity of the problem is PTIME-complete for sequential transition systems [KV96], we show that it is PSPACE-complete (rather than EXPTIME-complete) for concurrent transition systems. The reason for this anomaly is the fact that translating a strongly fair concurrent system into a sequential one indeed involves an exponential blow up in the number of states, but involves no such blow up in the size of the fairness condition. Evidently, it is the size of the fairness condition that is the dominant factor when reasoning about strongly-fair transition systems. This suggests that strong fairness is the preferable fairness condition to use when specifying concurrent programs. Not only is it the most expressive condition, but it also suffers less than
the others from the state-explosion problem.

2 Preliminaries

2.1 Fair Concurrent Transition Systems

A fair nondeterministic transition system with bounded concurrency (concurrent transition system, for short) is a tuple $S = \langle O, S_1, \ldots, S_n \rangle$ consisting of a finite set $O$ of observable events and $n$ components $S_1, \ldots, S_n$ for some $n \geq 1$. Each component $S_i$ is a tuple $\langle O_i, W_i, W_i^0, \delta_i, L_i, \alpha_i \rangle$, where:

- $O_i \subseteq O$ is a set of local observable events. The $O_j$ are not necessarily pairwise disjoint; hence, observable events may be shared by several components. We require that $O = \bigcup_{j=1}^{n} O_j$.
- $W_i$ is a finite set of states, and we require that the $W_j$ be pairwise disjoint. Also, we let $W = \bigcup_{j=1}^{n} W_j$.
- $W_i^0 \subseteq W_i$ is the set of initial states.
- $\delta_i \subseteq W_i \times B(W) \times W_i$ is a transition relation, where $B(W)$ denotes the set of all Boolean propositional formulas over $W$.
- $L_i : W_i \to 2^{O_i}$ is a labeling function that labels each state with a set of local observable events. The intuition is that $L_i(w)$ are the events that occur, or hold, in $w$.
- $\alpha_i$ is a fairness condition. We define three types of fairness conditions shortly. We require all the $\alpha_i$'s to be of the same type, which we refer to as the type of $S$.

Since states are labeled with sets of elements from $O$, we refer to $\Sigma = 2^O$ as the alphabet of $S$. While each component of $S$ has its local observable events and its own states and transitions, these transitions depend not only on the component’s current state but also on the current states of the other components. Also, as we shall now see, the labels of the components are required to agree on shared observable events.

A configuration of $S$ is a tuple $c = \langle w_1, w_2, \ldots, w_n, \sigma \rangle \in W_1 \times W_2 \times \cdots \times W_n \times \Sigma$, satisfying $L_i(w_i) = \sigma \cap O_i$ for all $1 \leq i \leq n$. Thus, a configuration describes the current state of each of the components, as well as the set of observable events labeling these states. The requirement on $\sigma$ implies that these labels are consistent, i.e., for any $S_i$ and $S_j$, and for each $o \in O_i \cap O_j$, either $o \in L_i(w_i) \cap L_j(w_j)$ (in which case, $o \in \sigma$), or $o \notin L_i(w_i) \cup L_j(w_j)$ (in which case, $o \notin \sigma$). For a configuration $c = \langle w_1, w_2, \ldots, w_n, \sigma \rangle$, we term $\langle w_1, w_2, \ldots, w_n \rangle$ the global state of $c$, and we term $\sigma$ the label of $c$, and denote it by $L(c)$. A configuration is initial if for all $1 \leq i \leq n$, we have $w_i \in W_i^0$. We use $C$ to denote the set of all configurations of a given system $S$, and $C_0$ to denote the set of all its initial configurations. We also use $c[i]$ to refer to $S_i$'s state in $c$. 

For a propositional formula $\theta$ in $B(W)$ and a global state $p = \langle w_1, w_2, \ldots, w_n \rangle$, we say that $p$ satisfies $\theta$ if assigning true to states in $p$ and false to states not in $p$ makes $\theta$ true. For example, $s_1 \land (t_1 \lor t_2)$, with $s_1 \in W_1$ and $\{t_1, t_2\} \subseteq W_2$, is satisfied by every global state in which $S_1$ is in state $s_1$ and $S_2$ is in either $t_1$ or $t_2$. We shall sometimes write disjunctions as sets, so that the above formula can be written $\{s_1\} \land \{t_1, t_2\}$. Formulas in $B(W)$ that appear in transitions are called conditions. If $\theta$ is equivalent to true in the transition $\langle w, \theta, w' \rangle$, we say that it is unconditional.

Given two configurations $c = \langle w_1, w_2, \ldots, w_n, \sigma \rangle$ and $c' = \langle w'_1, w'_2, \ldots, w'_n, \sigma' \rangle$, we say that $c'$ is a successor of $c$ in $S$, and write $\text{succ}_S(c, c')$, if for all $1 \leq i \leq n$ there is $\langle w_i, \theta, w'_i \rangle \in \delta_i$ such that $\langle w_1, w_2, \ldots, w_n \rangle$ satisfies $\theta_i$. In other words, a successor configuration is obtained by simultaneously applying to all the components a transition that is enabled in the current configuration. Note that by requiring that successors are indeed configurations, we are saying that transitions can only lead to states satisfying the consistency criterion, to the effect that they agree on the labels for shared observable events.\footnote{This requirement could obviously have been imposed implicitly in the transition relation, by disallowing in the $\delta_i$ any tuples $\langle w, \theta, w' \rangle$ for which $\theta$ holds when the states of some of the components are mutually inconsistent. Since we always want the components to agree on the labeling of shared observable events, we have set up our definitions of configurations and successors to make this requirement explicit. Technically, imposing the requirement in the transition relation could be done by replacing each condition $\theta$ by $\theta \land \varphi$, where $\varphi \in B(W)$ is satisfied in a global state exactly when the states of all its components are mutually consistent. The length of $\varphi$ is linear in $|W|$ and $|O|$, so that the explicit requirement does not involve a substantial decrease in succinctness.}

Given a configuration $c$, a $c$-computation of $S$ is an infinite sequence $\pi = c_0, c_1, \ldots$ of configurations, such that $c_0 = c$ and for all $i \geq 0$ we have $\text{succ}_S(c_i, c_{i+1})$. A computation of $S$ is a $c$-computation for some $c \in C_0$. The $c$-computation $c_0, c_1, \ldots$ generates the infinite trace $\rho \in \Sigma^\omega$, defined by $\rho = L(c_0) \cdot L(c_1) \cdots$. Sometimes we want to exclude computations of $S$ that do not meet some fairness criteria. This is particularly essential when we model concurrent programs and want to rule out computations that do not meet certain scheduling criteria. In order to determine whether a computation $\pi$ is fair, we refer to the sets of states that each of the components visits infinitely often along $\pi$. For each $1 \leq i \leq n$, let $\text{Inf}(\pi, i)$ denote the set of states that $S_i$ visits infinitely often. That is,

$$\text{Inf}(\pi, i) = \{w \in W_i : \text{for infinitely many } j \geq 0, \text{ we have } c_j[i] = w\}.$$  

Note that the set $\text{Inf}(\pi, i)$ considers only the states of $S_i$ and does not refer to the global states visited along $\pi$. For example, it might be that all $1 \leq i \leq n$ have some $w_i \in \text{Inf}(\pi, i)$ and still no configuration in $\pi$ has the global state $\langle w_1, \ldots, w_n \rangle$. The way we refer to $\text{Inf}(\pi, i)$ depends in the fairness condition of $S$. Several types of fairness conditions are studied in the literature. We consider here three:

- **Unconditional** fairness (or impartiality), where for all components $S_i$ we have $\alpha_i \subseteq 2^{W_i}$, and $\pi$ is fair if for all $1 \leq i \leq n$ and for every set $G \in \alpha_i$, we have $\text{Inf}(\pi, i) \cap G \neq \emptyset$.\footnote{This requirement could obviously have been imposed implicitly in the transition relation, by disallowing in the $\delta_i$ any tuples $\langle w, \theta, w' \rangle$ for which $\theta$ holds when the states of some of the components are mutually inconsistent. Since we always want the components to agree on the labeling of shared observable events, we have set up our definitions of configurations and successors to make this requirement explicit. Technically, imposing the requirement in the transition relation could be done by replacing each condition $\theta$ by $\theta \land \varphi$, where $\varphi \in B(W)$ is satisfied in a global state exactly when the states of all its components are mutually consistent. The length of $\varphi$ is linear in $|W|$ and $|O|$, so that the explicit requirement does not involve a substantial decrease in succinctness.}
• **Weak** fairness (or *justice*), where $\alpha_i \subseteq 2^{W_i} \times 2^{W_i}$, and $\pi$ is fair iff for all $1 \leq i \leq n$ and for every pair $(G, B) \in \alpha_i$, we have that $\text{Inf}(\pi, i) \cap (W_i \setminus G) = \emptyset$ implies $\text{Inf}(\pi, i) \cap B \neq \emptyset$.

• **Strong** fairness (or *fairness*), where $\alpha_i \subseteq 2^{W_i} \times 2^{W_i}$, and $\pi$ is fair iff for all $1 \leq i \leq n$ and for every pair $(G, B) \in \alpha_i$, we have that $\text{Inf}(\pi, i) \cap G \neq \emptyset$ implies $\text{Inf}(\pi, i) \cap B \neq \emptyset$.

In addition, we consider **non-fair concurrent transition systems**; i.e., concurrent transition systems in which all the computations are fair. For simplicity, we denote components of non-fair concurrent transition system by quintuplet, leaving $\alpha_i$ out.

We use $T(S^e)$ to denote the set of all traces generated by fair e-computations, and the trace set $T(S)$ of $S$ is then defined as $\bigcup_{e \in C_0} T(S^e)$. In this way, each concurrent transition system $S$ defines a subset of $\Sigma^\omega$. We say that $S$ accepts a trace $\rho$ if $\rho \in T(S)$. Also, we say that $S$ is *empty* if $T(S) = \emptyset$; i.e., $S$ has no fair computation, and that $S$ is *universal* if $T(S) = \Sigma^\omega$; i.e., every trace in $\Sigma^\omega$ is generated by some fair computation of $S$. Note that for a non-fair concurrent transition system $S$, the trace set $T(S)$ contains all traces $\rho \in \Sigma^\omega$ for which there exists a computation $\pi$ with $L(\pi) = \rho$.

The **size** of a concurrent transition system $S$ is the sum of the sizes of its components. Symbolically, $|S| = |S_1| + \cdots + |S_n|$. Here, for a component $S_i = \langle O_i, W_i, W^0_i, \delta_i, L_i, \alpha_i \rangle$, we define $|S_i| = |O_i| + |W_i| + |\delta_i| + |L_i| + |\alpha_i|$, where $|\delta_i| = \sum_{(w, \omega) \in \delta_i} |\theta|$, $|L_i| = |O_i| \cdot |W_i|$, and $|\alpha_i|$ is the sum of the cardinalities of the sets in $\alpha_i$. Clearly, $S$ can be stored in space $O(|S|)$.

When $S$ has a single component, we say that it is a **sequential transition system**. Note that the transition relation of a sequential transition system can be really viewed as a subset of $W \times W$, and that a configuration of a sequential transition system is simply a labeled state.

**Example 2.1** We construct a non-fair concurrent transition system $S$ as a binary counter; it counts up to $2^n$ in base 2 using $n$ components. Given $n$, let $S = \langle \{bit_1, \ldots, bit_n\}, S_1, \ldots, S_n \rangle$, where $S_i = \langle \{\text{bit}_i\}, \{w^0_i, w^1_i\}, \{w^0_i, w^1_i\}, \delta_i, L_i \rangle$, with $\delta_i$ and $L_i$ defined as follows:

- $\delta_i = \{\langle w^0_i, \theta_i, w^0_i, \rangle, \langle w^0_i, \theta_i, w^1_i, \rangle, \langle w^1_i, \theta_i, w^0_i, \rangle, \langle w^1_i, \theta_i, w^1_i, \rangle, \langle w^0_i, -\theta_i, w^0_i, \rangle, \langle w^0_i, -\theta_i, w^1_i, \rangle, \langle w^1_i, -\theta_i, w^0_i, \rangle, \langle w^1_i, -\theta_i, w^1_i, \rangle\}$, where $\theta_i = \bigvee_{j < i} w^0_j$. Note that $\theta_i = \text{false}$. Thus, $S_i$ corresponds to the least significant bit of the counter and always alternates between $w^0_i$ and $w^1_i$. The component $S_i$, for $i > 1$, switches between $w^0_i$ and $w^1_i$ whenever all the $S_j$ with $j < i$ are in their $w^1_j$ states. Otherwise, $S_i$ stays in its current state.

- For every $S_i$, we set $L_i(w^0_i) = \emptyset$ and $L_i(w^1_i) = \{\text{bit}_i\}$.

The single initial trace induced by the system $S$ is

$$\langle \emptyset, \{\text{bit}_1\}, \{\text{bit}_2\}, \{\text{bit}_2, \text{bit}_1\}, \{\text{bit}_3\}, \{\text{bit}_3, \text{bit}_1\}, \ldots, \{\text{bit}_n, \text{bit}_{n-1}, \ldots, \text{bit}_1\}\rangle^\omega.$$

Note that although $S$ has $n$ components, its size is quadratic in $n$. Indeed, the size of each transition relation $\delta_i$ is $O(i)$. However, we can define a slightly more sophisticated version of
this system that is of size $O(n)$. Each component $S_i$ has four states, corresponding to the possible values of both the $i$'th bit of the counter and the $i$'th carry bit. The conditions in the transitions in $\delta_i$ then refer only to the states of $S_{i-1}$, and are of a constant size.

2.2 Trace-Based and Tree-Based Implementations

The problems that formalize correct trace-based and tree-based implementations of a system are containment and simulation, respectively. Once we add fairness to the systems, the corresponding problems are fair containment and fair simulation. These problems are defined below with respect to two concurrent transition systems $S = \langle O, S_1, \ldots, S_n \rangle$ and $S' = \langle O', S'_1, \ldots, S'_m \rangle$ with $O \supseteq O'$, and with possibly different numbers of components. For technical convenience, we assume that $O = O'$ and that $S$ and $S'$ have the same type of fairness conditions.  

2.2.1 Containment and Fair Containment

The fair-containment problem for $S$ and $S'$ is to determine whether $\mathcal{T}(S) \subseteq \mathcal{T}(S')$. That is, whether every trace accepted by $S$ is also accepted by $S'$. When $S$ and $S'$ are non-fair, we call the problem containment. If $\mathcal{T}(S) \subseteq \mathcal{T}(S')$, we say that $S'$ contains $S$ and we write $S \subseteq S'$.

2.2.2 Simulation

While containment refers only to the set of computations of $S$ and $S'$, simulation refers also to the branching structure of the systems. Let $c$ and $c'$ be configurations of $S$ and $S'$, respectively. A relation $H \subseteq C \times C'$ is a simulation relation from $\langle S, c \rangle$ to $\langle S', c' \rangle$ iff the following conditions hold [Mil71].

1. $H(c, c')$.
2. For all configurations $a \in C$ and $a' \in C'$ with $H(a, a')$, we have $L(a) = L(a')$.
3. For all configurations $a \in C$ and $a' \in C'$ with $H(a, a')$ and for every configuration $b \in C$ such that $\text{succ}_S(a, b)$, there exists a configuration $b' \in C'$ such that $\text{succ}_{S'}(a', b')$ and $H(b, b')$.

A simulation relation $H$ is a simulation from $S$ to $S'$ iff for every $c \in C_0$ there exists $c' \in C'_0$ such that $H(c, c')$. If there exists a simulation from $S$ to $S'$, we say that $S$ simulates $S'$ and we write $S \preceq S'$. Intuitively, it means that the system $S'$ has more behaviors than the system $S$. In fact, every tree embodied in $S$ is also embodied in $S'$. The simulation problem is, given $S$ and $S'$, to determine whether $S \preceq S'$.

\footnote{Our results hold also for the general cases. Taking, for each $\sigma \in 2^O$, the letter $\sigma \cap O'$ instead the letter $\sigma$, adjusts all our algorithms to the case $O \supseteq O'$. Also, when $S$ and $S'$ have different types of fairness conditions, the type of $S$ is dominant, and the complexity of the problem is the same as in the case where both systems have fairness conditions of $S$'s type.}
2.2.3 Fair Simulation

Let $H \subseteq C \times C'$ be a relation over the configurations of $S$ and $S'$. It is convenient to extend $H$ to relate also computations of $S$ and $S'$. For two computations $\pi = c_0, c_1, \ldots$ in $S$, and $\pi' = c'_0, c'_1, \ldots$ in $S'$, we say that $H(\pi, \pi')$ holds iff $H(c_i, c'_i)$ holds for all $i \geq 0$. For a pair $\langle c, c' \rangle \in C \times C'$, we say that $\langle c, c' \rangle$ is good in $H$ iff for every fair $c$-computation $\pi$ in $S$, there exists a fair $c'$-computation $\pi'$ in $S'$, such that $H(\pi, \pi')$.

Let $c$ and $c'$ be configurations in $S$ and $S'$, respectively. A relation $H \subseteq C \times C'$ is a fair-simulation relation from $\langle S, c \rangle$ to $\langle S', c' \rangle$ iff the following conditions hold [GL94].

1. $H(c, c')$.
2. For all configurations $a \in C$ and $a' \in C'$ with $H(a, a')$, we have $L(a) = L(a')$.
3. For all configurations $a \in C$ and $a' \in C'$ with $H(a, a')$, the pair $\langle a, a' \rangle$ is good in $H$.

A fair-simulation relation $H$ is a fair simulation from $S$ to $S'$ iff for every $c \in C_0$ there exists $c' \in C'_0$ such that $H(c, c')$. If there exists a simulation from $S$ to $S'$, we say that $S$ fairly simulates $S'$ and we write $S \preceq S'$. Intuitively, it means that the concurrent transition system $S'$ has more fair behaviors than the concurrent transition system $S$. The fair-simulation problem is, given $S$ and $S'$, to determine whether $S \preceq S'$.

It is easy to see that simulation implies containment. That is, if $S \preceq S'$, then $S \subseteq S'$. The opposite, however, is not true. In Figure 1 we present two transition systems $S$ and $S'$ such that the trace sets of both transition systems is $a \cdot b \cdot (c^\omega + d^\omega)$. As such, $S \subseteq S'$, but still, $S$ does not simulate $S'$. Indeed, no state of $S'$ can be paired, by any $H$, to the state labeled $b$ of $S$ [Mil80].

![Figure 1: $S \subseteq S'$ but $S \not\preceq S'$](image)

We say that two concurrent transition systems $S$ and $S'$ are equivalent if they fairly simulate each other. Thus, if $S \preceq S'$ and $S' \preceq S$. Note that equivalent systems agree on their trace sets.

**Theorem 2.2** Every concurrent transition system $S$ can be translated into an equivalent sequential transition system of the same type and of size $2^{O(|S|)}$. 

9
**Proof:** Drusinsky and Harel prove the theorem with respect to automata, where the observable events are input to the machine and where equivalence is defined as agreement on the trace set [DH94]. Yet, their proof holds also for transition systems with our definition of equivalence (mutual simulation), as follows. Consider a concurrent transition system $S$ with $n$ components. The state space of its equivalent sequential transition system $S'$ is the Cartesian product of the state sets of the $n$ components (this would be $W_1 \times W_2 \times \cdots \times W_n$ in the notation used earlier). Thus, each state of $S'$ corresponds to a configuration of $S$. Accordingly, the transition relation of $S'$ coincides with the relation $\text{succ}_S$ over the configurations of $S$. We now need to define the fairness condition of $S'$ so that a computation of $S'$ is fair iff the corresponding computation of $S$ is fair. Let $\alpha'$ be such that for all $1 \leq i \leq n$, every set $G \in \alpha_i$ (pair $\langle G, B \rangle \in \alpha_i$) induces the set $W_1 \times \cdots \times W_{i-1} \times G \times W_{i+1} \times \cdots \times W_n$ (the pair $\langle W_1 \times \cdots \times W_{i-1} \times G \times W_{i+1} \times \cdots \times W_n, W_1 \times \cdots \times W_{i-1} \times B \times W_{i+1} \times \cdots \times W_n \rangle$, respectively) in $\alpha'$. It is easy to see that $S$ and $S'$ agree on their trace sets, that they simulate each other, and that the size of $S'$ is at most exponential in that of $S$.

In the rest of this paper we examine the traced-based and the tree-based approaches from a complexity-theoretic point of view. We consider and compare the complexity of the four problems. The different levels of abstraction in the implementation and the specification are reflected in their sizes. The implementation is typically much larger than the specification and it is its size that is the computational bottleneck. Therefore, of particular interest to us is the implementation complexity of these problems; i.e., the complexity of checking whether $S \subseteq S'$ and $S \preceq S'$, in terms of the size of $S$, assuming $S'$ is fixed.

### 2.3 Verification of Sequential Transition Systems

We mention here some known results on the verification of sequential transition systems.

**Theorem 2.3** [SVW87, VW94, KV96]

1. The containment problem for sequential transition systems is PSPACE-complete.

2. The implementation complexity of containment for sequential transition systems is NLOGSPACE-complete.

**Theorem 2.4** [Mil80, BGS92, KV96]

1. The simulation problem for sequential transition systems is PTIME-complete.

2. The implementation complexity of simulation for sequential transition systems is PTIME-complete.

**Theorem 2.5** [SVW87, VW94, KV96]
1. The fair-containment problem for sequential transition systems is PSPACE-complete.

2. The implementation complexity of fair-containment for sequential transition systems is NLOGSPACE-complete for unconditionally-fair and weakly-fair systems, and is PTIME-complete for strongly-fair systems.

Theorem 2.6 [KV96]

1. The fair-simulation problem for sequential transition systems is PSPACE-complete.

2. The implementation complexity of fair-simulation for sequential transition systems is PTIME-complete.

It follows that, when comparing the trace-based and the tree-based approaches to verification from a complexity-theoretic point to view, there is no clear advantageous approach. While the joint complexity of simulation is lower than that of containment, it is containment that has lower implementation complexity. In addition, fair containment and fair simulation have the same joint complexity, with fair containment having lower implementation complexity for the case of unconditionally-fair and weakly-fair transition systems.

3 The Containment Problem

Theorem 3.1 The containment problem for concurrent transition systems is EXPSPACE-complete.

Proof: Membership in EXPSPACE follows from Theorems 2.2 and 2.3.

To prove hardness, we carry out a reduction from deterministic exponential-space-bounded Turing machines. Given a Turing machine $T$ of exponential space complexity $s(n)$, we denote by $\Sigma$ an alphabet for encoding $T$ (the alphabet $\Sigma$ and the encoding are defined later). We then construct a transition system $S_T$ over the alphabet $\Sigma \cup \{\$\}$, for some $\$ \notin \Sigma$, such that (i) the size of $S_T$ is linear in $|T|$ and in $\log s(n)$, and (ii) $\Sigma^\omega + (\Sigma^* \cdot \$^\omega)$ \subseteq $T(S_T)$ iff $T$ does not accept the empty tape.

We assume, without loss of generality, that once $T$ reaches a final state it loops there forever. Typically, the transition system $S_T$ accepts all traces in $\Sigma^\omega$, and accepts a trace $w \cdot \$^\omega \in \Sigma^* \cdot \$^\omega$ if either

1. $w$ is not an encoding of a prefix of a legal computation of $T$ over the empty tape,

2. $w$ is an encoding of a prefix of a legal computation of $T$ over the empty tape, but, within this prefix, the computation still has not reached a final state, or

3. $w$ is an encoding of a prefix of a legal, but rejecting, computation of $T$ over the empty tape.
Thus, $S_T$ rejects a trace $w \cdot S^w$ iff $w$ encodes a prefix of a legal accepting computation of $T$ over the empty tape and the computation has already reached a final state. Hence, $S_T$ accepts all traces in $\Sigma^* \cdot S^w$ iff $T$ does not accept the empty tape.

Now to the details of the construction. Let $T = \langle \Gamma, Q, \mapsto, q_0, F_{\text{acc}}, F_{\text{rej}} \rangle$, where $\Gamma$ is the alphabet, $Q$ is the set of states, and $\mapsto: (Q \times \Gamma) \rightarrow (Q \times \Gamma \times \{L, R\})$ is the transition function. We write $(q, a) \mapsto (q', b, \Delta)$ for $\mapsto (q, a) = (q', b, \Delta)$, with the meaning that when in state $q$ and reading $a$ in the current tape cell, $T$ moves to state $q'$, writes $b$ in the current tape cell and moves its head one cell to the left or right, depending on $\Delta$. Finally, $q_0$ is $T$’s initial state, $F_{\text{acc}} \subseteq Q$ is the set of final accepting states, and $F_{\text{rej}} \subseteq Q$ is the set of final rejecting states.

We encode a configuration of $T$ by a string in $\# \Gamma^*(Q \times \Gamma)^*$, of the form $\# \gamma_1 \gamma_2 \cdots (q, \gamma_i) \cdots \gamma_{s(n)}$. The meaning of this is that the $j$’th cell, for $1 \leq j \leq s(n)$, is labeled $\gamma_j$, $T$ is in state $q$ and its head points to the $i$’th cell. Thus, if we denote the empty cell by $\beta$, then $T$’s initial configuration is $\# (q_0, \beta, \beta, \ldots \beta)$ (with $s(n) - 1$ occurrences of $\beta$).

We encode a computation of $T$ by a sequence of configurations, which is really a word over $\Sigma = \{\#\} \cup \Gamma \cup (Q \times \Gamma)$. Let $\sigma_1 \ldots \sigma_{s(n)} \# \sigma'_1 \ldots \sigma'_{s(n)}$ be two successive configurations of $T$ in such a sequence. (Here, each $\sigma_i$ is in $\Sigma$.) If we set $\sigma_0 = \sigma_{s(n)+1} = \#$ and consider a triple $\langle \sigma_{i-1}, \sigma_i, \sigma_{i+1} \rangle$, for $1 \leq i \leq s(n)$, it is clear that the transition function of $T$ prescribes $\sigma'_i$. In addition, along the encoding of the entire computation, $\#$ must repeat exactly every $s(n) + 1$ letters. Let $\text{next}(\sigma_{i-1}, \sigma_i, \sigma_{i+1})$ denote our expectation for $\sigma'_i$. That is, with the $\gamma$’s denoting elements of $\Gamma$, we have:

- $\text{next}(\gamma_{i-1}, \gamma_i, \gamma_{i+1}) = \text{next}(\#, \gamma_i, \gamma_{i+1}) = \text{next}(\gamma_{i-1}, \gamma_i, \#) = \gamma_i$.
- $\text{next}((q, \gamma_{i-1}), \gamma_i, \gamma_{i+1}) = \text{next}((q, \gamma_{i-1}), \gamma_i, \#) = \begin{cases} \gamma_i & \text{if } (q, \gamma_{i-1}) \mapsto (q', \gamma'_i, L) \\ (q', \gamma_i) & \text{if } (q, \gamma_{i-1}) \mapsto (q', \gamma'_i, R) \end{cases}$
- $\text{next}(\gamma_{i-1}, (q, \gamma_i), \gamma_{i+1}) = \text{next}(\#, (q, \gamma_i), \gamma_{i+1}) = \text{next}(\gamma_{i-1}, (q, \gamma_i), \#) = \gamma_i'$, where $(q, \gamma_i) \mapsto (q', \gamma_i', \Delta)$.
- $\text{next}(\gamma_{i-1}, (q, \gamma_i), (q, \gamma_{i+1})) = \text{next}(\#, (q, \gamma_i), (q, \gamma_{i+1})) = \begin{cases} \gamma_i & \text{if } (q, \gamma_{i+1}) \mapsto (q', \gamma'_{i+1}, L) \\ (q', \gamma_i) & \text{if } (q, \gamma_{i+1}) \mapsto (q', \gamma'_{i+1}, R) \end{cases}$
- $\text{next}(\sigma_{s(n)}, \#, \sigma'_1) = \#$.

A necessary and sufficient condition for a trace to encode a legal computation of $T$ on the empty tape is that it starts with the initial configuration and consecutive configurations are compatible with $\text{next}$.

Now for the construction of $S_T$. For traces in $\Sigma^* \cdot S^w$, we set up one of $S_T$’s components, $S_1$, to check that the trace encodes a legal computation. For that, $S_1$ checks whether the first configuration is the initial configuration, and whether the trace is compatible with $\text{next}$. In

---

3We assume that $T$’s head does not “fall” from the right or the left boundaries of the tape. Thus, the case where $i = 1$ and $(q, \gamma_i) \mapsto (q', \gamma'_i, L)$ and the dual case where $i = s(n)$ and $(q, \gamma_i) \mapsto (q', \gamma'_i, R)$ are not possible.
order to check whether the first configuration is the initial configuration, \( S_T \) simply compares the first \( s(n) + 1 \) letters with \( \#(q_0, \beta) \beta \ldots \beta \). In order to check compatibility with \( \text{next} \), \( S_1 \) uses nondeterminism to guess where there is a violation of \( \text{next} \). Thus, \( S_1 \) guesses a triple \( (\sigma_{i-1}, \sigma_i, \sigma_{i+1}) \in \Sigma^3 \), guesses a position in the trace, checks whether the three letters to be read starting at this position are indeed \( \sigma_{i-1}, \sigma_i, \) and \( \sigma_{i+1} \), and checks whether \( \text{next}(\sigma_{i-1}, \sigma_i, \sigma_{i+1}) \) is not the letter appearing \( s(n) + 1 \) letters later. In order to count to \( s(n) + 1 \), the component \( S_1 \) cooperates with the log \( s(n) \) other components, whose only task is to perform this count (as described in Example 2.1). Once \( S_1 \) sees a violation of the initial configuration or of \( \text{next} \), it goes to a sink labeled \$$. This takes care of traces of the form \( w \cdot \$^w \in \Sigma^* \cdot \$^w \), for which \( w \) is not an encoding of a prefix of a legal computation of \( T \) over the empty tape. In order to handle the other two types of \( w \) that should be accepted, \( S_1 \) may move to the sink labeled \$$ also as long as no configuration with a final state (one with \( q \in F_{\text{acc}} \cup F_{\text{rej}} \)) is found in the input, and after a configuration with a final rejecting state (one with \( q \in F_{\text{rej}} \)) is found in the input. In addition, \( S_1 \) accepts all traces in \( \Sigma^w \) (say, by having \( |\Sigma| \) additional initial states arranged in a clique). It is easy to see that \( |S_T| \) is linear in \( |T| \) and in \( \log s(n) \).

Now, we construct \( S \) to be a concurrent transition system that generates the language \( \Sigma^w + (\Sigma^* \cdot \$^w) \). In fact, \( S \) can be easily taken to be a sequential transition system with \( |\Sigma| + 1 \) states. It follows that \( T \) does not accept the empty tape iff \( S \subseteq S_T \).

\[ \square \]

The reduction we present in the proof of Theorem 3.1 considers a simple implementation and an elaborated specification. We now show that the specification is indeed the dominant factor of the containment problem. Fixing it, the problem becomes significantly easier. Still, traversing the exponentially big state space of the implementation cannot be avoided.

**Theorem 3.2** The implementation complexity of containment for concurrent transition systems is PSPACE-complete.

**Proof:** Membership in PSPACE follows from Theorems 2.2 and 2.3. For the lower-bound, we prove that the emptiness problem for concurrent transition systems is already PSPACE-hard. For that, we carry out a reduction from deterministic polynomial-space-bounded Turing machines. We show that given a deterministic Turing machine \( T \) of polynomial space complexity \( s(n) \), it is possible to build, using a logarithmic amount of space, a concurrent transition system \( S_T \) of size \( O(s(n)) \) such that \( S_T \) is empty if and only if \( T \) does not accept the empty tape.

Let \( T = \langle \Gamma, Q, \rightarrow, q_0, F_{\text{acc}}, F_{\text{rej}} \rangle \) be a deterministic Turing machine defined as in the proof of Theorem 3.1. The system \( S_T \) has \( s(n) \) components, one for each tape cell that is used. For all \( 1 \leq i \leq s(n) \), the component \( S_i = \langle O_i, W_i, W_i^0, \delta_i, L_i \rangle \) is defined as follows:

\( \bullet \) \( O_i = \emptyset \).
• $W_i = (((Q \setminus F_{rej}) \times \Gamma) \cup \Gamma) \times \{i\}$. A state of the form $(q, a, i)$ indicates that $T$ is in state $q$ and its head is at the $i$'th cell, whose contents is $a$. A state of the form $(a, i)$ indicates that the contents of the $i$'th cell is $a$ but the head is not at that cell.

• Each transition $(q, a) \mapsto (q', b, \Delta)$ of $T$, with $q' \notin F_{rej}$, induces the following transitions in $\delta_i$.
  
  - An unconditional transition from $(q, a, i)$ to $(b, i)$; i.e., $\langle (q, a, i), \text{true}, (b, i) \rangle \in \delta_i$. This transition corresponds to the head moving from cell $i$ to cell $i + 1$ or $i - 1$.
  
  - A transition from every $(z, i) \in \Gamma \times \{i\}$ to $(q', z, i)$, with condition defined as follows:
    * If $\Delta = R$, then the current state of $S_{i-1}$ is $(q, a, i - 1)$; i.e., if $\Delta = R$, then $\langle (z, i), \{(q, a, i - 1)\}, (q', z, i) \rangle \in \delta_i$. (Thus, the condition is the single proposition “$(q, a, i - 1)$”.)
    * If $\Delta = L$, then the current state of $S_{i+1}$ is $(q, a, i + 1)$; i.e., if $\Delta = L$, then $\langle (z, i), \{(q, a, i + 1)\}, (q', z, i) \rangle \in \delta_i$.

  This transition corresponds to the head moving from cell number $i + 1$ or $i - 1$ to cell number $i$.

In addition, we have a transition in $\delta_i$ from every $(z, i) \in \Gamma \times \{i\}$ to $(z, i)$, with a condition stating that the head is not moving now to the $i$'th cell. Let $W^i_R$ be the set of states $(q, a, i - 1)$ in $W_{i-1}$ such that $(q, a) \mapsto (q', b, R)$ is a transition of $T$ for some $q'$ and $b$. In a dual way, let $W^i_L$ be the set of states $(q, a, i + 1)$ in $W_{i+1}$ such that $(q, a) \mapsto (q', b, L)$ is a transition of $T$ for some $q'$ and $b$. Then, $\langle (z, i), (W^i_R \cup W^i_L), (z, i) \rangle \in \delta_i$. (Recall that we use sets like $W^i_R$ and $W^i_L$ to stand for disjunctions in our condition formulas).

• $W^0_i$, the set of initial states of $S_i$, is a singleton that corresponds to the initial contents of the $i$'th cell. Thus, $W^0_i = \{(q_0, \beta, 1)\}$ for $i = 1$, and $W^0_i = \{\langle \beta, i \rangle\}$ for $1 < i \leq s(n)$.

• The function $I_i$ labels all states with $\emptyset$.

Since $T$ is deterministic, the system $S_T$ proceeds in a deterministic fashion, which corresponds to the single computation of $T$ on the empty tape. To see this, observe that each reachable configuration of $S_T$ has exactly one component $S_i$ which is in a state in $Q \times \Gamma \times \{i\}$. Thus, each reachable configuration of $S_T$ corresponds to a configuration of $T$. Also, a transition in $S_T$ from configuration $c$ to $c'$ corresponds to the single possible transition of $T$ from its configuration corresponding to $c$ to the one corresponding to $c'$. Since states in $F_{rej} \times \Gamma \times \{i\}$ are not reachable in $W_i$, the system $S_T$ gets stuck whenever $T$ moves to a final rejecting state. So, if $T$ rejects the empty tape, then $S_T$ is empty. In addition, if $T$ accepts the empty tape, then, as $T$ loops in its final state, $S_T$ accepts the trace $\emptyset^\omega$. Hence, $T$ rejects the empty tape iff $S_T$ is empty.
In view of the known PSPACE lower bound for emptiness in communicating finite state machines [Koz77], our PSPACE lower bound here is not surprising. Note, however, that the bound in [Koz77] does not directly imply our bound here, since concurrent transition systems generate infinite traces.

4 The Simulation Problem

Establishing simulation involves only local checks. One could hope that locality circumvents the state-explosion problem. We show here that while locality neutralizes the dominance of the specification, an exponential blow-up in the implementation cannot be avoided. Moreover, the branching nature of simulation can be used to encode alternation, making the implementation complexity of simulation higher than that of containment.

Theorem 4.1 The simulation problem for concurrent transition systems is EXPTIME-complete.

Proof: Membership in EXPTIME follows from Theorems 2.2 and 2.4. To prove hardness in EXPTIME, we carry out a reduction from alternating linear-space-bounded Turing machines, proved to be EXPTIME-hard in [CKS81]. Similarly to the construction in the proof of Theorem 3.2, we show that there exists a fixed concurrent transition system $S'$, such that, given an alternating Turing machine $T$ of space complexity $s(n)$, it is possible to build, using a logarithmic amount of space, a concurrent transition system $S_T$ of size $O(s(n))$ such that $S \preceq S'$ if and only if $T$ accepts the empty tape.

Consider an alternating Turing machine $T = \langle \Gamma, Q_u, Q_e, \rightarrow, q_0, F_{acc}, F_{rej} \rangle$, where the four sets of states, $Q_u, Q_e, F_{acc}$, and $F_{rej}$ are disjoint, and contain the universal, the existential, the accepting, and the rejecting states, respectively. We denote their union (the set of all states) by $Q$. Our model of alternation prescribes that $\rightarrow \subseteq Q \times \Gamma \times Q \times \Gamma \times \{L, R, H\}$ has a binary branching degree, is universal in its even-numbered steps, and is existential in its odd-numbered ones. ($H$ means that the head of $T$ stays on the same cell.) In particular, $q_0 \in Q_e$. When a universal or an existential state of $T$ branches into two states, we distinguish between the left and the right branches. Accordingly, we use $(q, a) \mapsto ((q_l, b_l, \Delta_l), (q_r, b_r, \Delta_r))$ to indicate that when $T$ is in state $q \in Q_u \cup Q_e$ reading input symbol $a$, it branches to the left with $(q_l, b_l, \Delta_l)$ and to the right with $(q_r, b_r, \Delta_r)$. (Note that the directions left and right here have nothing to do with the movement direction of the head; these are determined by $\Delta_l$ and $\Delta_r$.) We term $q_l$ the $\preceq$-child of $q$, and $q_r$ its $\succeq$-child. Finally, we assume that once $T$ reaches a final state, it loops there forever in a deterministic fashion. Accordingly, we use $(q, a) \mapsto (q, a, H)$ to indicate that when $T$ is in state $q \in F_{acc} \cup F_{rej}$ reading symbol $a$, it stays in the same configuration.

The possible computations of $T$ on $w$ induce an AND-OR graph, whose nodes are $T$'s configurations. We say that a node corresponds to state $q$ if $T$'s state in the node's configuration is $q$. With each node in the graph we associate an acceptance value in $\{0, 1\}$ as follows. Nodes that correspond to states in $F_{acc}$ (respectively, $F_{rej}$) have acceptance value 1 (respectively, 0),
The acceptance value of an AND-node (which corresponds to a universal state) is the minimum of the acceptance values of its two children, and that of an OR-node (which corresponds to an existential state) is the maximum of the acceptance values of its two children.

We now construct the fixed transition system $S'$. The intention is for $S'$ to embody all possible AND-OR graphs that may be induced by accepting computations of all alternating Turing machines (using the model of alternation just described). The system $S'$ has a single component (thus, it is really a sequential transition system), whose 20 states “model” such machines as follows:

- Eight states model the Turing machine’s universal states. Each of these states matches an entry in the truth table of the operator $\land$, adorned with a direction, either $\lor$ or $\land$, and a flag $\land$ that indicates that this is a universal state. Thus, if for simplicity we leave out the commas separating the elements, the universal internal states of $S'$ are $\langle \land 000 \lor \rangle$, $\langle \land 010 \lor \rangle$, $\langle \land 100 \lor \rangle$, $\langle \land 111 \lor \rangle$, $\langle \land 000 \land \rangle$, $\langle \land 010 \land \rangle$, $\langle \land 100 \land \rangle$, and $\langle \land 111 \land \rangle$.

- Eight states model the Turing machine's existential states. These match the entries of the truth table of $\lor$, adorned with a direction and a flag $\lor$. Thus, the existential internal states of $S'$ are $\langle \lor 000 \lor \rangle$, $\langle \lor 011 \lor \rangle$, $\langle \lor 101 \lor \rangle$, $\langle \lor 111 \lor \rangle$, $\langle \lor 000 \land \rangle$, $\langle \lor 011 \land \rangle$, $\langle \lor 101 \land \rangle$, and $\langle \lor 111 \land \rangle$.

- Four states model the Turing machine’s final states. Each of these is a Boolean value, adorned with a direction. Thus, the final states of $S'$ are $\langle 0 \lor \rangle$, $\langle 1 \lor \rangle$, $\langle 0 \land \rangle$, and $\langle 1 \land \rangle$.

The intuition is that an internal state $\langle *, l, r, val, d \rangle$ corresponds to a state of the Turing machine with the following properties: Its left child has acceptance value $l$, right child has acceptance value $r$, its own acceptance value is, therefore, $val$, and it can be only a $d$-child of other states. Similarly, a final state $\langle val, d \rangle$ corresponds to a final state of the Turing machine with acceptance value $val$ (that is, if $val = 1$ then the state is in $F_{\text{acc}}$ and if $val = 0$ then it is in $F_{\text{rej}}$), that can be only a $d$-child of other states.

Accordingly, the transitions in $S'$ from an internal state $\langle *, l, r, val, d \rangle$ cover all the possible ways that $l$ and $r$ can be acceptance values of the left and right children, respectively. Thus, we have transitions from $\langle *, l, r, val, d \rangle$ to another state $w = \langle *, l', r', val', d' \rangle$ iff $w$ is an internal state of the opposite type (i.e., either $* = \land$ and $* = \lor$, or vice versa) or $w = \langle val', d' \rangle$ is a final state, and, in both cases, either $val' = l$ and $d' = \lor$, or $val' = r$ and $d' = \land$. For example, the internal state $\langle \land 100 \lor \rangle$ has transitions to states $\langle \lor 011 \lor \rangle$, $\langle \lor 101 \lor \rangle$, $\langle \lor 111 \lor \rangle$, $\langle \lor 000 \land \rangle$, $\langle 1 \lor \rangle$, and $\langle 0 \land \rangle$. It has transitions from all states $\langle \lor, l, r, val, d \rangle$ with $l = 0$. In addition, the final states have self loops.

The set of observable events of $S'$ is $\{ \lor, \land, 0, 1 \}$. We label an internal state by $\lor$ or $\land$ according to its direction element. For example, the node $\langle \land 100 \lor \rangle$ is labeled $\{ \lor \}$. We label a final state by its value and direction. For example, the node $\langle 1 \land \rangle$ is labeled $\{ 1, \land \}$. We define the initial states of $S'$ to be the internal existential states with $val = 1$. 
This completes the definition of \( S' \). Clearly, it’s size is fixed.

Given a particular alternating Turing machine \( T \), we now define the system \( S_T \) such that \( S_T \leq S' \) iff \( T \) accepts the empty tape. In general, the construction of \( S_T \) is similar to that in the proof of Theorem 3.2. The main difference is that while \( T \) there was deterministic, \( T \) here is alternating, and it branches in each of its transitions. Therefore, moving from configuration to configuration we must take extra care to ensure that either all components move according to the left branch, or all components move according to the right branch.

Let \( T = \langle \Gamma, Q_u, Q_r, \rightarrow, q_0, F_{acc}, F_{rej} \rangle \) be an \( s(n) \)-space-bounded alternating Turing machine as described above. The concurrent transition system \( S_T \) has \( s(n) \) components, one for each tape cell. For each \( 1 \leq i \leq s(n) \), the component \( S_i = \langle O_i, W_i, W_0^i, \delta_i, L_i \rangle \) is defined as follows:

- \( O_i = \{\nearrow, \searrow, 0, 1\} \). Thus, \( O_i = O \), and the sets of observable events are thus independent of \( i \). As we shall see below, the events \( \nearrow \) and \( \searrow \) guarantee that all components move according to the same branch.

- \( W_i = (\{(Q \times \Gamma) \cup \Gamma\} \times \{\nearrow, \searrow\} \times \{i\} \). A state of the form \((q, a, d, i)\) is called a head-content state; it indicates that \( T \) is in state \( q \), the head is at cell \( i \), whose content is \( a \), and \( q \) was reached by taking a \( d \) branch. A state of the form \((a, d, i)\) is called a content state; it indicates that the content of cell \( i \) is \( a \), the head is not at cell \( i \), and if the previous state of \( S_i \) was a head-content state then the current state has become a content state as a result of a taking a \( d \) branch. For both types of states, we call \( d \) the direction element. The direction element of a content state is determined once there is a transition from some head-content state to it. The direction element is guaranteed to maintain the directionality of the branch taken in this transition only for the next configuration. Later, this direction element may be changed.

- \( S_T \)'s transitions are induced by the transitions of \( T \) as follows (in the following description we ignore the borderline cases of \( i = 1 \) or \( i = s(n) \), which are essentially the same but require a little more attention).

  - Each transition \((q, a) \rightarrow \langle (q_l, b_l, \Delta_l), (q_r, b_r, \Delta_r) \rangle \) of \( T \) induces the following transitions in \( \delta_i \):

    1. Unconditional transitions that correspond to the head moving from cell \( i \) to cell \( i+1 \) or \( i-1 \). These transitions also determine the direction element of the new state of \( S_i \). For \( d \in \{\nearrow, \searrow\} \), we have

       \[ \langle (q, a, d, i), \text{true}, (b_l, \nearrow, i) \rangle \in \delta_i \text{ and } \langle (q, a, d, i), \text{true}, (b_r, \searrow, i) \rangle \in \delta_i. \]

    2. Transitions that correspond to the head moving from cell \( i+1 \) or \( i-1 \) to cell \( i \), as a result of taking a left branch. This includes a transition from every state \((z, d, i) \in \Gamma \times \{\nearrow, \searrow\} \times \{i\} \) to the state \((q_l, z, \nearrow, i) \), with the following conditions:
* If $\Delta_t = R$, then the current state of $S_{i-1}$ must be $(q, a, d', i - 1)$ for some $d' \in \left\{ \emptyset, \gamma \right\}$; i.e., if $\Delta_t = R$, then

$$
\langle (z, d, i), \{ (q, a, \emptyset, i - 1), (q, a, \gamma, i - 1) \}, (q_r, z, \emptyset, i) \rangle \in \delta_i.
$$

* If $\Delta_t = L$, then the current state of $S_{i+1}$ must be $(q, a, d', i + 1)$ for some $d' \in \left\{ \emptyset, \gamma \right\}$; i.e., if $\Delta_t = L$, then

$$
\langle (z, d, i), \{ (q, a, \emptyset, i + 1), (q, a, \gamma, i + 1) \}, (q_r, z, \emptyset, i) \rangle \in \delta_i.
$$

3. Dual transitions that correspond to the head moving from cell $i + 1$ or $i - 1$ to cell $i$, as a result of taking a right branch. This includes a transition from every state $(z, d, i) \in \Gamma \times \left\{ \emptyset, \gamma \right\} \times \{ i \}$ to the state $(q_r, z, \emptyset, i)$, with the following conditions:

* If $\Delta_r = R$, then the current state of $S_{i-1}$ must be $(q, a, d', i - 1)$ for some $d' \in \left\{ \emptyset, \gamma \right\}$; i.e., if $\Delta_r = R$, then

$$
\langle (z, d, i), \{ (q, a, \emptyset, i - 1), (q, a, \gamma, i - 1) \}, (q_r, z, \emptyset, i) \rangle \in \delta_i.
$$

* If $\Delta_r = L$, then the current state of $S_{i+1}$ must be $(q, a, d', i + 1)$ for some $d' \in \left\{ \emptyset, \gamma \right\}$; i.e., if $\Delta_r = L$, then

$$
\langle (z, d, i), \{ (q, a, \emptyset, i + 1), (q, a, \gamma, i + 1) \}, (q_r, z, \emptyset, i) \rangle \in \delta_i.
$$

- For each transition $(q, a) \mapsto (q, a, H)$ of $T$, and for all $d \in \left\{ \emptyset, \gamma \right\}$, we have an unconditional transition that corresponds to looping in the final state $q$; i.e.,

$$
\langle (q, a, d, i), \text{true}, (q, a, d, i) \rangle \in \delta_i.
$$

- In addition, we have transitions that correspond to “passive” cells; that is, cells to which or from which the head does not move. We allow these cells to change their direction elements, so they can adjust themselves to the new configurations, both the one that corresponds to taking the left branch and the one that corresponds to taking the right branch. This includes transitions from each state $(z, d, i) \in \Gamma \times \left\{ \emptyset, \gamma \right\} \times \{ i \}$ to states $(z, d', i)$ for $d' \in \left\{ \emptyset, \gamma \right\}$, with the condition that if a $d'$ branch is currently taken, the head is not moving to cell $i$. For this, we define the following four sets of states for each $1 \leq i \leq s(n)$:

- $W_{Rl}^i$ is the set of states $(q, a, d, i - 1)$ in $W_{i-1}$ for which there is a transition $(q, a) \mapsto \langle (q, b, 1), (q_r, b_r, \Delta_r) \rangle$ of $T$ for some $q_l, b_l, q_r, b_r$ and $\Delta_r$. Thus, whenever $S_{i-1}$ is in a state in $W_{Rl}^i$, then in the configuration obtained by taking the left branch, the component $S_i$ is in a head-content state. The other three sets are defined in a dual way.

- $W_{Rr}^i$ is the set of states $(q, a, d, i - 1)$ in $W_{i-1}$ for which there is a transition $(q, a) \mapsto \langle (q_l, b_l, \Delta_l), (q_r, b_r, R) \rangle$ of $T$ for some $q_l, b_l, q_r, \Delta_r$ and $b_r$. 

18
* $W^i_{L_i}$ is the set of states $(q, a, i+1)$ in $W_{i+1}$ for which there is a transition $(q, a) \mapsto ((q_i, b, L), (q_r, b_r, \Delta_r))$ of $T$ for some $q_i, b_i, q_r, b_r$ and $\Delta_r$.

* $W^i_{R_i}$ is the set of states $(q, a, d, i+1)$ in $W_{i+1}$ for which there is a transition $(q, a) \mapsto ((q_i, b, i), (q_r, b_r, L))$ of $T$ for some $q_i, b_i, q_r, \Delta_i, q_r$ and $\Delta_r$.

Now,

$\langle (z, d, i), -(W^i_{R_i} \cup W^i_{L_i}), (z, \vee, i) \rangle \in \delta_i$ and $\langle (z, d, i), -(W^i_{R_i} \cup W^i_{L_i}), (z, \wedge, i) \rangle \in \delta_i$.

Note that when the head is not moving to or from cell $i$, the component $S_i$ can change its direction element.

- The set of initial states of $S_i$ is a singleton that corresponds to the initial content of cell $i$ with (the arbitrarily chosen) direction element $\vee$. Thus, this set will be $\{(q_0, \beta, \vee, 1)\}$ for $i = 1$, and $\{(\beta, \vee, i)\}$ for $1 < i \leq s(n)$.

- The labeling function $L_i$ is defined as follows:
  - $\vee \in L_i(w)$ iff $w \in ((Q \times \Gamma) \cup \Gamma) \times \{\vee\} \times \{i\}$.
  - $\wedge \in L_i(w)$ iff $w \in ((Q \times \Gamma) \cup \Gamma) \times \{\wedge\} \times \{i\}$.
  - $0 \in L_i(w)$ iff $w \in F_{rej} \times \Gamma \times \{\vee, \wedge\} \times \{i\}$.
  - $1 \in L_i(w)$ iff $w \in F_{acc} \times \Gamma \times \{\vee, \wedge\} \times \{i\}$.

We claim that the unwinding of the system $S_T$ corresponds to the AND-OR graph induced by the possible computations of $T$ on the empty tape. To see this, observe that each reachable configuration of $S_T$ has exactly one component $S_i$ in a head-content state. All other components are in content states. It is true that often two components can move into head-content states, but then, by the definition of $\delta_i$, they will have different direction elements, which implies, by the definition of $L_i$, that there will be disagreement on the labeling of $\vee$ and $\wedge$. Thus, each reachable configuration of $S_T$ corresponds to a legal configuration of $T$. Also, each configuration of $S_T$ either corresponds to a universal or existential state of $T$ (in which case it has exactly two possible successors, one for each possible branch) or corresponds to a final state of $T$ (in which case it has one possible successor and is labeled by either 0 or 1). Accordingly, we term the configurations of $S_T$ universal, existential, or final.

For the formal proof, let us define the depth of a configuration $c$ of $S_T$ as the length of the longest path from $c$ to a final configuration. Thus, for a final configuration $c$ we have $\text{depth}(c) = 0$ and for a universal or an existential configuration with two successors $c_l$ and $c_r$, we have $\text{depth}(c) = 1 + \max\{\text{depth}(c_l), \text{depth}(c_r)\}$. Let $H$ be a simulation relation from $S_T$ to $S'$. We prove that for every configuration $c$ of $S_T$ the following hold.

- If $\text{depth}(c) = 0$ and $H(c, w)$, for some state $w$ of $S'$, then $w = \langle \text{val}, d \rangle$ and the acceptance value of $c$ is $\text{val}$.
• If $\text{depth}(c) \geq 1$ and $H(c, w)$, for some state $w$ of $S'$, then $w = \langle *, l, r, val, d \rangle$ and the acceptance value of $c$ is $val$.

The proof proceeds by induction on $\text{depth}(c)$. Consider first the case $\text{depth}(c) = 0$. Then, $c$ is a final configuration. Let $H(c, w)$. Since only final configurations of $S_T$ and final states of $S'$ are labeled by elements in \{0, 1\}, it must be that $w$ is a final state; that is, $w = \langle val, d \rangle$. In addition, the definition of the labels in $S_T$ and $S'$ implies that the acceptance value of $c$ is $val$, and we are done. Assume now that the claim holds for all configurations of depth at most $i$. Let $c$ be such that $\text{depth}(c) = i + 1$ and let $H(c, w)$. Then, $c$ must be either a universal or an existential configuration, and again, by the definition of the labels in $S_T$ and $S'$, it must be that $w$ is an internal state; that is, $w = \langle *, l, r, val, d \rangle$. By the way we model alternation, $T$ starts in an existential state and alternates every step. Also, by the definition of $S'$, its initial states can only be internal existential states. Consequently, $H$ can relate existential configurations of $S_T$ only to existential internal states of $S'$, and similarly for universal states. Consider the case where $c$ is a universal configuration. By the definition of simulation, for every successor $c'$ of $c$ in $S_T$ there exists a successor $w'$ of $w$ in $S'$ such that $H(c', w')$. We know that $c$ has two successors, $c_l$ and $c_r$. Let $w_l$ and $w_r$ be the states of $S'$ with $H(c_l, w_l)$ and $H(c_r, w_r)$. Note that the states $w_l$ and $w_r$ may be final or internal states. In both cases, however, their “full names” contain $val_l$ and $val_r$, respectively, such that, by the induction hypothesis, the acceptance value of $c_l$ is $val_l$ and the acceptance value of $c_r$ is $val_r$. By the definition of $S'$ we have $val = \text{AND}(val_l, val_r)$. Also, the acceptance value of $c$ is the minimum of the acceptance values of $c_l$ and $c_r$. Hence, the acceptance value of $c$ is $val$ and we are done. The case where $c$ is an existential configuration is similar.

We can now prove formally that $T$ accepts the empty tape iff $S_T \leq S'$. Assume first that $S_T \leq S'$. Then, there exists a simulation relation $H$ from $S_T$ to $S'$. Since the initial configuration of $S_T$ corresponds to the initial configuration of $T$, and since the initial states of $S'$ are these with $val = 1$, then, by the above claim, the acceptance value of the initial configuration of $T$ is 1. Therefore, $T$ accepts the empty tape.

For the other direction, assume that $T$ accepts the empty tape. Consider a relation $H$ from the states of $S_T$ to the states of $S'$ in which $H(c, \langle val, d \rangle)$ holds for a final configuration $c$ iff $val$ is the acceptance value of $c$ and $d \in L(c)$, and in which $H(c, \langle *, l, r, val, d \rangle)$ holds for a universal or an existential configuration $c$ iff $*$ is the type of $c$, $l$ is the acceptance value of the $\vee$-child of $c$, $r$ is the acceptance value of the $\wedge$-child of $c$, $val$ is the acceptance value of $c$, and $L(c) = \{d\}$. We prove that $H$ is a simulation relation from $S_T$ to $S$, thus $S_T \leq S'$. Consider a configuration $c$ of $S_T$ with $H(c, w)$. We have to show that for every successor $c'$ of $c$ there exists a successor $w'$ of $w$ such that $H(c', w')$. Consider first the case where $c$ is a final configuration. Then, by the definition of $S_T$, which loops in its final configurations, the configuration $c$ has a single successor $c'$ with $c' = c$. By the definition of $H$, the state $w$ is a final state. As such, it has, by the definition of $S'$, a single successor $w'$ with $w' = w$. Hence, $H(c', w')$. Consider now the case where $c$ is a universal configuration. By the definition of $H$,
the state $w$ is of the form $\langle \land, l, r, \text{val}, d \rangle$, where $l$ is the acceptance value of the $\land$-child of $c$, $r$ is the acceptance value of the $\land$-child of $c$, $\text{val}$ is the acceptance value of $c$, and $L(c) = \{d\}$. By the definition of $S_T$, the configuration $c$ has as successors two configurations $c_l$ and $c_r$. Consider the configuration $c_l$. Note that $\land \in L(c_l)$. We distinguish between two cases. First, if $c_l$ is a final configuration, let $w_l = \langle \text{val}_l, \land \rangle$ be a successor of $w$ for which $\text{val}_l$ is the acceptance value of $c_l$. Second, if $c_l$ is an existential configuration (note that $c_l$ cannot be a universal configuration), let $w_l = \langle \lor, l_l, r_l, \text{val}_l, \land \rangle$ be a successor of $w$ for which $l_l$ is the acceptance value of the $\land$-child of $c_l$, $r_l$ is the acceptance value of the $\lor$-child of $c_l$, and $\text{val}_l$ is the acceptance value of $c_l$. By the definition of $S'$, such a successor $w_l$ exists in both cases. Also, by the definition of $H$, we have $H(c_l, w_l)$ and we are done. The proof for the configuration $c_r$ and for the case where $c$ is an existential configuration are similar. 

**Theorem 4.2** The implementation complexity of simulation for concurrent transition systems is EXPTIME-complete.

**Proof:** Membership in EXPTIME follows from Theorem 4.1. Since the transition system $S'$ used there is fixed, the proof of Theorems 4.1 provides an EXPTIME lower bound also for the implementation complexity of the simulation problem. 

5 The Fair-Containment and the Fair-Simulation Problems

So far, we saw that when we consider non-fair transition systems, verification of concurrent transition systems is exponentially harder than verification of sequential transition systems. We now turn to consider fair transition systems.

**Theorem 5.1** The fair-containment problem for concurrent transition systems is EXPSPACE-complete.

**Proof:** Membership in EXPSPACE follows from Theorems 2.2 and 2.5. Hardness in EXPSPACE follows from Theorem 3.1. 

Theorem 5.1 shows that, as in the case of sequential transition systems, the trace-based approach to verification extends to fair systems at no cost. Indeed, the complexities of containment and fair containment coincide. An exception to this phenomenon are strongly fair transition systems. By Theorem 2.5, the implementation complexity of fair containment for strongly-fair systems is higher than the implementation complexity of containment. We now show that strongly-fair transition systems are exceptional also in their concurrent behavior: The implementation complexity of fair containment for concurrent strongly-fair systems is not exponentially harder than that of sequential strongly-fair systems.
**Theorem 5.2** The implementation complexity of the fair-containment problem for concurrent transition systems is PSPACE-complete.

**Proof:** Hardness in PSPACE follows from Theorem 3.2. For unconditionally-fair and weakly-fair concurrent transition systems, membership in PSPACE follows from Theorems 2.2 and 2.5. For strongly-fair systems, a straightforward application of Theorems 2.2 and 2.5 results in an algorithm with exponential running time. To get the PSPACE bound, we suggest the following algorithm. Let $S$ and $S'$ be strongly fair concurrent transition systems, and let $D$ be a strongly-fair sequential transition system equivalent to $S$. For each component $S_i$ of $S$, let $k_i$ and $m_i$ denote the number of states and the number of pairs in the fairness condition of $S_i$, respectively. Assume that $S$ has $n$ components. Then, following the construction described in the proof of Theorem 2.2, the system $D$ has $k = k_1 \cdot k_2 \cdots k_n$ states and $m = m_1 + m_2 + \cdots + m_k$ pairs in its fairness condition. By [KV96], we can translate $D$ to an unconditionally-fair sequential transition system $U$ with $k \cdot 2^{O(m)}$ states. Thus, the size of $U$ is exponential in the size of $S$. We can also translate $S'$ to an unconditionally-fair sequential transition system $U'$ (this also involves an exponential blow up, which, as $S'$ is fixed, is irrelevant to our proof). By Theorem 3.2, checking the containment of $U$ in $U'$ can be done nondeterministically in space logarithmic in $U$, thus polynomial in $S$, and we are done. \[\square\]

**Theorem 5.3** The fair-simulation problem for concurrent transition systems is EXPSPACE-complete.

**Proof:** Membership in EXPSPACE follows from Theorems 2.6 and 2.2. To prove hardness in EXPSPACE we do a reduction from exponential-space-bounded Turing machines. Our reduction is similar to the reduction described in [KV96] for proving a lower bound to the fair-simulation problem for sequential transition systems. The only change is that while there the Turing machines are polynomial-space bounded, yielding a PSPACE lower bound, here the machines are exponential-space bounded, yielding an EXPSPACE lower bound. Using bounded concurrency, we can handle the exponential size of the tape by $n$ components that count to $2^n$. The details of the reduction are given below.

For a set $O$ of observable events (with $\Sigma = 2^O$), let $S_\Sigma$ be the sequential transition system $\langle O, \Sigma, \Sigma, \Sigma \times \Sigma, L_\Sigma, \emptyset \rangle$, where for all $\sigma \in \Sigma$ we have $L_\Sigma(\sigma) = \sigma$. That is, each state in $S_\Sigma$ is associated with a letter $\sigma \in \Sigma$ and $T(S_\Sigma) = \sigma \cdot \Sigma^\omega$. It is easy to see that the system $S_\Sigma$ is universal (recall that a system $S$ is universal if $T(S) = \Sigma^\omega$). Therefore, a concurrent transition system $S$ over $O$ is universal iff $S_\Sigma \subseteq S$. It is not true, however, that $S$ is universal iff $S_\Sigma \subseteq S$. While $S_\Sigma \subseteq S$ implies that $S_\Sigma \subseteq S$ and thus, that $S$ is universal, it may be that $S$ is universal and still there is no fair simulation from $S$ to $S_\Sigma$. A necessary and sufficient condition for the existence of such a simulation is that each configuration $c$ of $S$ satisfies $T(S') = L(c) \cdot \Sigma^\omega$. Then, a relation that maps a state $\sigma$ of $S_\Sigma$ to all the configurations of $S$ that are labeled with $\sigma$ is a fair simulation.
Given a Turing machine $T$ of exponential space complexity $s(n)$ (the machine $T$ is given as a tuple as described in the proof of Theorem 3.1), let $T'$ be as follows. Whenever $T$ reaches an accepting configuration, $T'$ "cleans" the tape and starts from the beginning (i.e., empty tape and initial state at the left end of the tape). Thus, $T$ accepts the empty tape iff $T'$ has an infinite computation, in which case it visits the initial configuration infinitely often. Let $\Sigma$ be the alphabet for encoding $T'$. We define a concurrent transition system $S'_T$ such that $S_\Sigma \preceq S'_T$ iff $T$ does not accept the empty tape. We describe here the construction for $S'_T$ that is strongly fair. As detailed in [KV96], similar constructions exist for unconditionally and weakly fair systems as well.

We first define a concurrent transition system $S_T$ as the union of two concurrent transition systems $S^1_T$ and $S^2_T$ with the following behaviors. Reading a trace $\rho$, the transition system $S^1_T$ checks for a violation of the transition relation of $T'$ in $\rho$ (by guessing a violation of next). If $S^1_T$ sees a violation, it goes to an accepting sink. The details of the construction of $S^1_T$ are similar to those described in the proof of Theorem 3.1. As there, one component of $S^1_T$ checks the trace. For that, it cooperates with other log $s(n)$ components that only perform the counting required for checking compatibility with next. Reading a trace $\rho$, the transition system $S^2_T$ checks for occurrence of the initial configuration of $T$ in $\rho$. If $S^2_T$ sees the initial configuration in a strict suffix of $\rho$, it goes to a rejecting sink. Since the initial configuration starts with $\#$ and has no other $#$ in it, it is easy to check its occurrence. Therefore, $S^2_T$ can be defined as a sequential transition relation. Consequently, assuming the state spaces of $S^1_T$ and $S^2_T$ are disjoint, it is easy to define the union of $S^1_T$ and $S^2_T$. (E.g., by adding to each component of the transition system $S^1_T$ a copy of $S^2_T$, defining the initial set of the component to be the union of the initial sets of itself and these of $S^2_T$, and defining its fairness condition to be the union of its pairs and the pairs in $S^2_T$).

It follows that the transition system $S_T$ accepts a trace $\rho$ if $\rho$ violates next or never visit the initial configuration, except possibly as the first configuration. Thus, $S_T$ does not accept a trace $\rho$ iff $\rho$ does not violate next and it visits the initial configuration of $T$ in some strict suffix of it. Therefore, $S_T$ is universal iff $T$ does not accept the empty tape. Indeed, since $T'$ revisit the initial configuration iff $T$ reaches an accepting configuration, a trace not accepted by $S_T$ corresponds to an accepting computation of $T$ on the empty tape, and vice versa.

We want, however, more than universality test. We want to define a transition system $S'_T$ in such a way that if it is indeed universal, then for each of its configurations $c$, we have $T(S''_T) = L(c) \cdot \Sigma^\omega$. Then, recall, it is true that $S'_T$ is universal iff $S_\Sigma \preceq S'_T$. Let $S_i = \langle O_i, W_i, W_i^0, \delta_i, L_i, \alpha_i \rangle$ be a component of $S_T$. We assume that $\delta_i \cap (W_i \times W_i^0) = \emptyset$. Thus, for all components $S_i$ of $S_T$, no computation of $S_T$ visits states from $W_i^0$ more than once (this can be easily achieved by duplicating states in $W_i^0$ that are visited more than once). We define the components $S'_i$ of the transition system $S'_T$ by adding to each component $S_i$ of $S_T$ transitions from all states to all the initial states, with the requirement that these transitions can be taken only finitely often. Accordingly, $S'_i = \langle O_i, W_i, W_i^0, \delta_i \cup (W_i \times W_i^0), L_i, \alpha_i \cup \langle W_i^0, \emptyset \rangle \rangle$. Let $C'$ and $C'_0$ be the sets of configurations and initial configurations of $S'_T$, respectively. We claim the
following:

(1) $S'_T$ is universal iff for each $\sigma \in \Sigma$, there exists $c_0 \in C'_0$ with $L(c_0) = \sigma$ and for each $c \in C'$ we have $T(S''_T^c) = L(c) \cdot \Sigma^\omega$.

(2) $S_T$ is universal iff $S'_T$ is universal.

We start with Claim (1). First, if for each $\sigma \in \Sigma$ there exists $c_0 \in C'_0$ with $L(c_0) = \sigma$, and for each $c \in C'$ we have $T(S''_T) = L(c) \cdot \Sigma^\omega$, then clearly $T(S''_T) = \Sigma^\omega$; thus $S_T$ is universal. For the other direction, consider some trace $\rho \in \Sigma^\omega$. Let $\sigma$ be the first letter in $\rho$. By the assumption, there exists $c_0 \in C'_0$ with $L(c_0) = \sigma$. In addition, as $T(S''_T) = \sigma \cdot \Sigma^\omega$, we have that $\rho \in T(S''_T)$. Hence, $\rho$ is accepted by $S'_T$. Since $\rho$ may be any trace in $\Sigma^\omega$, it follows that $S'_T$ is universal.

We now prove Claim (2). Clearly, every computation $\pi$ of $S_T$ is a computation in $S'_T$. Since no component of $S_T$ visits its initial state more than once along a computation, adding the pair $\langle W^1, 0 \rangle$ to the acceptance conditions $\alpha_i$, we still have that if $\pi$ is fair in $S_T$ then it is also fair in $S'_T$. Hence, $T(S_T) \subseteq T(S'_T)$, and therefore, if $S_T$ is universal, so is $S'_T$. Assume now that $S_T$ is not universal. Consider a trace $\rho$ not accepted by $S_T$. Recall that $\rho$ does not violate next and it visits the initial configuration of $T$ in some strict suffix of it. In other words, $\rho$ is of the form $yx$ where $y$ is a prefix not violating next and $x$ is an infinite computation of $T'$ (the initial configuration of $T$ is the first configuration encoded in $x$). An infinite computation of $T'$ visits the initial configuration infinitely often. Therefore, all the suffixes of $\rho$ are of that special form! Hence, if $\rho$ is not accepted by $S_T$, all its suffixes are also not accepted by $S_T$.

We show that this implies that $\rho$ is not accepted by $S'_T$ too. Assume, by way of contradiction, that $\rho$ is accepted by $S'_T$. Let $\pi = c_0, c_1, \ldots$ be a fair computation of $S'_T$ with $L(\pi) = \rho$. By the acceptance conditions of the components of $S'_T$, there exists $k \geq 0$ such that for all $j > k$, and for all components $S'_j$, we have $c_j[1] \not\in W^1$. Hence, for all $j \geq k$, we have $\text{succ}_{S_T}(c_j, c_{j+1})$. Therefore, the computation $\pi^k = c_k, c_{k+1}, \ldots$ is a fair computation in $S_T$, and the trace $L(\pi^k)$ is accepted by $S_T$, contradicting the fact it is a suffix of a trace not accepted by $S_T$.

As discussed above, Claims (1) and (2) now imply that $S_S \leq S'_T$ iff $S_T$ is universal, thus $S_S \leq S'_T$ iff $T$ does not accept the empty tape. Since the fairness conditions of $S_T$ and $S'_T$ can be specified in terms of either unconditional, weak, or strong fairness, we are done.

**Theorem 5.4** The implementation complexity of the fair-simulation problem for concurrent transition systems is EXPTIME-complete.

**Proof:** Membership in EXPTIME follows from Theorems 2.6 and 2.2. Hardness in EXPTIME follows from Theorem 4.2.
6 Discussion

Our results are illustrated by the cube figures below, in the style of [Har89, DH94]. All the complexities denote tight bounds. We use $J$ to denote joint complexity (and its omission to denote implementation complexity), $F$ to denote fair transition systems (and its omission to denote non-fair ones), and $C$ to denote concurrent transition systems (and its omission to denote sequential ones). A bold arrow represents an exponential gap between the complexity classes, a dashed arrow represents a transition from a certain space-complexity class to the same time-complexity class, and a dotted line represents a transition from a certain time-complexity class to the space-complexity class it subsumes.

**Containment:**

**Simulation:**

This paper considered the upper planes of the boxes. The vertical bold arrows illustrate the state-explosion problem, which is unavoidable. The protruding vertex on the lower level of the containment cube illustrates the anomaly of the strong fairness condition.

How robust are our results? Examining our lower-bound proofs, one can observe that they employ only a very humble kind of cooperation between the components. Indeed, in all the reductions, the conditions used in the transitions of a certain component $S_i$ refer only to states of the components $S_{i-1}$ and $S_{i+1}$. This suggests that a very weak, and local, model of concurrency is sufficient in order to cause the state-explosion problem. In particular, our results hold for the concurrency models presented in CSP and CCS.
