Abstract
We introduce and study a game variant of the classical spanning-tree problem. Our spanning-tree game is played between two players, MIN and MAX, who alternate turns in jointly constructing a spanning tree of a given connected weighted graph $G$. Starting with the empty graph, in each turn a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges form a spanning tree in $G$.

The goal of MIN is to minimize the weight of the resulting spanning tree and the goal of MAX is to maximize it. A strategy for a player is a function that maps each forest in $G$ to an edge that is not yet in the forest and does not close a cycle.

We show that while in the classical setting a greedy approach is optimal, the game setting is more complicated: greedy strategies, namely ones that choose in each turn the lightest (MIN) or heaviest (MAX) legal edge, are not necessarily optimal, and calculating their values is NP-hard.

We study the approximation ratio of greedy strategies. We show that while a greedy strategy for MIN guarantees nothing, the performance of a greedy strategy for MAX is satisfactory: it guarantees that the weight of the generated spanning tree is at least $w(MST(G))$, where $w(MST(G))$ is the weight of a maximum spanning tree in $G$, and its approximation ratio with respect to an optimal strategy for MAX is $1.5 + \frac{1}{w(MST(G))}$, assuming weights in $[0, 1]$. We also show that these bounds are tight. Moreover, in a stochastic setting, where weights for the complete graph $K_n$ are chosen at random from $[0, 1]$, the expected performance of greedy strategies is asymptotically optimal. Finally, we study some variants of the game and study an extension of our results to games on general matroids.

1 Introduction

The fundamental minimum (respectively, maximum) spanning tree problem receives as an input a connected edge-weighted undirected graph and searches for a spanning tree, namely

an acyclic subgraph that connects all vertices, with a minimum (respectively, maximum) weight. The problem can be solved efficiently \cite{19, 26}. It has attracted much attention, has led to a lot of research on algorithms, and has many applications \cite{28, 10, 14}.

We introduce and study a natural game variant of the classical problem. Our spanning-tree game is played between two players, MIN and MAX, who alternate turns in jointly constructing a spanning tree of a given connected weighted graph \( G = \langle V, E, w \rangle \). Starting with the empty graph, in each turn a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges form a spanning tree in \( G \), that is, after \( |V| - 1 \) turns. The goal of MIN is to minimize the weight of the resulting spanning tree and the goal of MAX is to maximize it. A strategy for a player is a function that maps each forest in \( G \) to one of its legal moves, namely, it maps a forest \( F \subseteq E \) to an edge \( e \in E \setminus F \) such that \( F \cup \{e\} \) is also a forest. Given two strategies \( \pi_{\text{max}} \) and \( \pi_{\text{min}} \), we define the outcome of \( \pi_{\text{max}} \) and \( \pi_{\text{min}} \) as the spanning tree obtained when MAX and MIN follow \( \pi_{\text{max}} \) and \( \pi_{\text{min}} \), respectively, in a turn-based game in which MAX moves first. The value of a strategy \( \pi_{\text{max}} \) of MAX is the minimum over all strategies \( \pi'_{\text{min}} \) of MIN of the weight of the spanning tree that is the outcome of the game in which MAX follows \( \pi_{\text{max}} \) and MIN follows \( \pi'_{\text{min}} \). Then, an optimal strategy for MAX is a strategy with a maximum value. Thus, an optimal strategy for MAX is one that obtains the maximal value against the most hostile behavior (intuitively, the “most minimizing” strategy) of MIN. The value of a strategy for MIN is defined dually. In particular, an optimal strategy for MIN is one that obtains the minimal value against the “most maximizing” strategy for MAX. In this paper we focus on values of strategies of MAX.

Indeed, unless we bound the ratio between the weights of the heaviest and lightest edges in the graph, we cannot bound the “damage” that MAX can cause MIN, namely the ratio between the performance of min strategies and the minimum spanning tree, making the study of the game setting from the viewpoint of MIN less interesting.

\textbf{Example 1.} Consider the weighted graph \( G \) appearing in Figure 1 (a). The weight of \( G \)’s (unique, in this example) maximum spanning tree is 33 (see (b)). An optimal strategy for MAX chooses in its first two moves the edges with weights 5 and 4, leading, against an optimal strategy of MIN, to the spanning tree of weight 31 appearing in (c).

The transition from the classical one-player setting of the spanning-tree problem to a two-player setting corresponds to a transition from closed systems, which are completely under our control, to open systems, in which we have to contend with adversarial environments. Such a transition has been studied in computer science in logic \cite{8, 27}, complexity \cite{6}, and temporal reasoning \cite{23}, and it attracts growing attention now in algorithmic game theory, cf. \cite{24}. Our work here studies this transition in graph theory. For the basic problem of

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig1.png}
\caption{A weighted graph (a), its maximal spanning tree (b), and the outcomes of an optimal strategy (c) and a greedy one (d).}
\end{figure}
reachability, the two-player setting has given rise to alternating graph reachability [8]. We find it very interesting to study how other basic problems and concepts in graph algorithms evolve when we shift to a two-player setting [20]. Several graph games of this type were previously studied. For example, consider the general setting in which MAX and MIN alternately claim edges of a graph $G$ while making sure the graph they build together satisfies some monotone decreasing property. The Turán numbers and Saturation numbers refer to the number of edges that can be claimed while the property is maintained [13, 17]. Likewise, researchers have studied the game chromatic number of $G$, namely the smallest $k$ for which MIN has a strategy to color all vertices in a game in which MAX and MIN alternately properly color the vertices of $G$ using the colors $\{1, \ldots, k\}$ [1]. Finally, a game variant of the maximum-flow problem, where the algorithm can direct the flow only in a subset of the vertices is studied in [21].

Before we continue to describe our results, let us survey several games that have been studied and are based on minimum or maximum spanning trees. In the cooperative minimum cost spanning tree game [7, 2], the cost allocation between users of a minimum spanning tree is considered. Different properties of this cooperative game have been studied, such as the core and the nucleolus [15, 16], the Shapley value [18], and more [11]. The Stackelberg minimum spanning tree game [4, 5] is a one-round two-player network pricing game. The game is played on a graph, whose edges are colored either red or blue, with the red edges having a given fixed cost. The first player chooses an assignment of prices to the blue edges, and the second player then buys the cheapest possible minimum spanning tree, using any combination of red and blue edges. The goal of the first player is to maximize the total price of purchased blue edges. Shannon’s switching game is another related two-player game. Two players take turns coloring the edges of an arbitrary graph. One player has the goal of connecting two distinguished vertices by a path of edges of her color. The other player aims to prevent this by using her color instead (or, equivalently, by erasing edges) [22, 3].

The classical maximum spanning-tree problem can be solved efficiently. Indeed, the forests embodied in a graph induce a matroid [25], and thus a greedy approach is optimal. Accordingly, in Kruskal’s algorithm [19] for the maximum spanning-tree problem, the edges are chosen in a greedy manner, where in each step an edge with a maximum weight that does not close a cycle is added.

We study greedy strategies in the spanning-tree game. There, MAX always chooses an edge with a maximum weight that does not close a cycle. We first show that the game setting is indeed more complicated. First, greedy strategies are not necessarily optimal. For example, in the graph from Example 1, a greedy strategy for MAX chooses in its first three moves the edges with weight $8, 7, \text{and } 6$, leading to the spanning tree of weight 27 appearing in Figure 1 (d). In addition, we show that given a strategy for MAX, it is NP-complete to calculate its value, and NP-hardness holds already for greedy strategies. Subsequently, we turn to study how well greedy strategies for MAX perform. We evaluate them with respect to the value of the maximum spanning tree, and with respect to the value of an optimal strategy for MAX. We analyze both the general and stochastic settings. We view our findings in both evaluations as good news. Indeed, greedy strategies for MAX ensure surprisingly tight approximations in all cases.

It is not hard to see that the value of any greedy strategy for MAX is at least half the weight of a maximum spanning tree. Indeed, the tree generated by such a strategy includes at least the heavier half of the set of edges that are chosen by a greedy algorithm in the classical setting. Much harder is the study of the approximation ratio of a greedy strategy for MAX with respect to an optimal strategy for her. We show that when the weight of
the maximum spanning tree tends to infinity, the approximation ratio tends to 1.5. More formally, assuming that the weights are normalized to values in $[0, 1]$ (note that such a normalization does not affect the ratio between the values of different strategies), we show an approximation ratio of $1.5 + \frac{1}{\min\text{MST}(G)}$, where $w\text{(MST}(G))$ is the weight of a maximum spanning tree of $G$. We show that our results are tight: for every odd integer $n \geq 1$, there exists a weighted graph $G = \langle V, E, w \rangle$ with $w\text{(MST}(G)) = 2n$, such that the value of the greedy strategy for MAX is $n$, whereas the value of an optimal strategy is $\lceil \frac{n}{2} \rceil + n$. Thus, the ratio between the maximal spanning tree and the value of the greedy strategy is 2, and the ratio between the values of the optimal and the greedy strategies is $1.5 + \frac{1}{\min\text{MST}(G)}$. We also show that, unlike the case of greedy strategies of MAX, one cannot bound the approximation ratio of greedy strategies of MIN. As we elaborate in Section 7, since the set of forests that are subgraphs of a given graph form the family of independent sets of a matroid, many of our results go beyond the spanning-tree problem and apply to matroids in a game setting.

We then study the approximation ratio of greedy strategies for MAX in a stochastic setting. Namely, we study the game played on complete graphs whose edge-weights are chosen by a uniform distribution over $[0, 1]$. Building on results of [12] regarding the weight of maximum and minimum spanning trees in such randomly weighted graphs, we are able to show that, in this setting, the approximation ratio of any greedy max strategy is asymptotically almost surely (a.a.s., for brevity) 1. Thus, while in the worst case the approximation ratio is 2 with respect to a maximum spanning tree and it tends to 1.5 with respect to an optimal strategy, it is a.a.s. 1 when we choose the edge-weights uniformly at random.

Finally, we study two variants of the setting. First, a finer definition of an approximation ratio, where performance of a strategy for MAX is examined with respect to all strategies of MIN, and second, a two-turn variant of the game, where MAX first chooses a forest of size $k$, for a parameter $k$ of the game, and then MIN completes the forest to a spanning tree.

## 2 Preliminaries

### 2.1 Graphs and Weighted Graphs

An undirected graph is a pair $G = \langle V, E \rangle$, where $V$ is a finite set and $E$ is a set of pairs of elements of $V$. We refer to the elements of $V$ as vertices and to the elements of $E$ as edges. A graph may contain parallel edges. A path in $G$ is a sequence of vertices $v_1, v_2, \ldots, v_k$ such that $\langle v_i, v_{i+1} \rangle \in E$ for all $1 \leq i < k$. A cycle in $G$ is a path $v_1, v_2, \ldots, v_k$ for which $v_1 = v_k$. A graph $G = \langle V, E \rangle$ is connected if for every two vertices $v, v' \in V$, there is a path between $v$ and $v'$ in $G$. A tree is a connected graph with no cycles. A forest is a graph with no cycles, namely a collection of trees. A spanning tree of $G$ is a tree $\langle V, T \rangle$, for a subset $T \subseteq E$. Note that the size of a spanning tree is $n - 1$. When the set $V$ of vertices is clear from the context, we describe trees and forests by their sets of edges only.

A weighted graph $G = \langle V, E, w \rangle$ augments a graph with a weight function $w : E \rightarrow \mathbb{R}^+$. We extend $w$ to subsets of $E$ in the expected way, i.e., $w : 2^E \rightarrow \mathbb{R}^+$ is such that for all $A \subseteq E$, we have $w(A) = \sum_{e \in A} w(e)$. In the maximum spanning tree problem, we are given a weighted graph $G$ and seek a spanning tree for $G$ of a maximum weight. Note that $G$ may have several maximum spanning trees. By abuse of notation, we use $\text{MST}(G)$ to denote any maximum spanning tree of $G$. 

2.2 Matroids

A finite matroid $\mathcal{M}$ is a pair $(\mathcal{E}, \mathcal{I})$, where $\mathcal{E}$ is a finite set (called the ground set) and $\mathcal{I}$ is a family of subsets of $\mathcal{E}$ (called the independent sets) that satisfies the following three properties: (1) $\mathcal{I}$ is not empty, (2) The hereditary property: If $X \in \mathcal{I}$ and $Y \subseteq X$, then $Y \in \mathcal{I}$, and (3) The independent set exchange property: If $X$ and $Y$ are in $\mathcal{I}$ and $|X| > |Y|$, then there is an element $x \in X \setminus Y$ such that $Y \cup \{x\}$ is in $\mathcal{I}$.

For a graph $G = (V, E)$, let $\mathcal{F}_G$ be the set of forests in $G$. The pair $(E, \mathcal{F}_G)$ is a matroid and is called the cycle matroid of $G$ (see, e.g., [25]).

2.3 The Spanning-Tree Game

We consider a game variant of the maximum spanning tree problem: there are two players, $\text{MAX}$ and $\text{MIN}$, who alternate turns in jointly constructing a spanning tree of a given weighted graph. Starting with the empty graph, in each turn, a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges are forming a spanning tree, that is, after $n - 1$ turns. The goal of $\text{MIN}$ is to minimize the weight of the resulting spanning tree and the goal of $\text{MAX}$ is to maximize it. Formally, we have the following.

Let $G = (V, E, w)$ be a weighted graph, and let $\mathcal{F}_G$ be the set of all forests $F \subseteq E$. A configuration in the spanning-tree game is a forest $F \in \mathcal{F}_G$. Let $M : \mathcal{F}_G \to 2^E$ be a function that maps a configuration $F$ to the set of all legal moves for a player when the game is in $F$. Formally, $M(F) = \{e \in E \setminus F :$ the graph $(V, F \cup \{e\})$ has no cycles$\}$.

A strategy for a player is a function $\pi : \mathcal{F}_G \to E$ that maps each configuration to one of its legal moves. Thus, for all $F \in \mathcal{F}_G$, we have $\pi(F) \in M(F)$. If $M(F) = \emptyset$ (that is, when $F$ is already a spanning tree), then $\pi(F)$ is undefined. Given two strategies $\pi_{\text{max}}$ and $\pi_{\text{min}}$, we define the outcome of $\pi_{\text{max}}$ and $\pi_{\text{min}}$, denoted $T(\pi_{\text{max}}, \pi_{\text{min}})$, as the spanning tree obtained when $\text{MAX}$ and $\text{MIN}$ follow $\pi_{\text{max}}$ and $\pi_{\text{min}}$, respectively, in a turn-based game in which $\text{MAX}$ moves first. Formally, $T(\pi_{\text{max}}, \pi_{\text{min}}) = \{e_1, \ldots, e_{n-1}\}$ is such that for all $1 \leq i \leq n - 1$, the following holds.

$$e_i = \begin{cases} \pi_{\text{max}}(\{e_1, e_2, \ldots, e_{i-1}\}) & \text{if } i \text{ is odd,} \\ \pi_{\text{min}}(\{e_1, e_2, \ldots, e_{i-1}\}) & \text{if } i \text{ is even.} \end{cases}$$

We use $w(\pi_{\text{max}}, \pi_{\text{min}})$ to denote the weight of $T(\pi_{\text{max}}, \pi_{\text{min}})$. Thus, $w(\pi_{\text{max}}, \pi_{\text{min}}) = w(T(\pi_{\text{max}}, \pi_{\text{min}}))$.

We refer to a strategy for $\text{MAX}$ as a max strategy and to a strategy for $\text{MIN}$ as a min strategy. Note that $\text{MAX}$ moves when the current configuration has an even number of edges, and $\text{MIN}$ moves when the configuration has an odd number of edges. Let $\mathcal{F}_G^{\text{even}}$ and $\mathcal{F}_G^{\text{odd}}$ be the subsets of $\mathcal{F}_G$ that contain forests of even and odd sizes, respectively. Let $\Pi_{\text{max}}$ and $\Pi_{\text{min}}$ be the set of all possible strategies for the $\text{MAX}$ and $\text{MIN}$ players, respectively. By the above, $\Pi_{\text{max}}$ contains strategies $\pi_{\text{max}} : \mathcal{F}_G^{\text{even}} \to E$ and $\Pi_{\text{min}}$ contains strategies $\pi_{\text{min}} : \mathcal{F}_G^{\text{odd}} \to E$. We evaluate a max strategy $\pi_{\text{max}}$ by its performance against a best

---

3 We could have defined $\pi$ to return a special signal, say $\perp$, in this case, but we ignore it and assume that the game ends after $n - 1$ rounds, so there is no need to apply a strategy from configurations that are spanning trees.

4 Formally, by our definition of a strategy, every strategy for $\text{MAX}$ and every strategy for $\text{MIN}$ should have a well-defined legal move for every configuration in $\mathcal{F}_G$. We have chosen to restrict the definition of such strategies only to the configurations they might actually encounter during play. For completeness, one can define them for all the remaining configurations arbitrarily or, again, by using the symbol $\perp$. 

MFCS 2018
(that is, most minimizing) min strategy. Formally, we define the value of a max strategy by
\[ \text{val}_{\text{max}}(\pi_{\text{max}}) = \min \{ w(\pi_{\text{max}}, \pi_{\text{min}}) : \pi_{\text{min}} \in \Pi_{\text{min}} \}. \]

Since the number of strategies is finite, the above expression always has a minimum and is thus well defined. Dually, we evaluate a min strategy \( \pi_{\text{min}} \) by its performance against a best (that is, most maximizing) max strategy. Formally, we define the value of a min strategy by
\[ \text{val}_{\text{min}}(\pi_{\text{min}}) = \max \{ w(\pi_{\text{max}}, \pi_{\text{min}}) : \pi_{\text{max}} \in \Pi_{\text{max}} \}. \]

Our study here focuses on max strategies. Essentially, our choice follows from the fact that, unlike the case of min strategies, one cannot bound the ratio between the outcome of an optimal or a greedy min strategy and the minimum spanning tree. Intuitively, it follows from the fact that the performance of strategies is strongly related to our ability to guarantee a favorable outcome even if we can control only half of the choices. Such a control guarantees that MAX can add to the spanning tree at least half of the heaviest edges in a maximum spanning tree. Such a control also guarantees that MIN can add to the spanning tree at least half of the lightest edges in a minimum spanning tree. Without, however, a bound on the ratio between the heaviest and lightest edge, such a guarantee is not of much help. In Appendix A, we motivate this choice further and present some results on min strategies.

The following lemma is an easy useful observation on the amount of control MAX and MIN have on the outcome of the game.

\[ \text{Lemma 2.} \text{ Let } G = (V,E,w) \text{ be a weighted graph and let } F \text{ be a forest of } G. \text{ Then, MAX has a strategy to ensure that the outcome includes at least } \lceil |F|/2 \rceil \text{ edges of } F, \text{ and MIN has a strategy to ensure that the outcome includes at least } \lfloor |F|/2 \rfloor \text{ edges of } F. \]

\[ \text{Proof.} \text{ We prove our claim for MIN; the proof for MAX is analogous. It suffices to show that, in each of his first } \lfloor |F|/2 \rfloor \text{ moves, MIN can claim an edge of } F. \text{ For every } 1 \leq i \leq \lfloor |F|/2 \rfloor, \text{ let } e_1, \ldots, e_{2i-1} \text{ denote the edges claimed by both players up until MIN’s } i-\text{th move. In his } i-\text{th move, MIN claims an arbitrary edge } e_2i \in F \setminus \{e_1, \ldots, e_{2i-1}\} \text{ such that } \{e_1, \ldots, e_{2i-1}, e_{2i}\} \text{ spans a forest. Such an edge } e_{2i} \text{ exists since } |F| > 2i - 1 = |\{e_1, \ldots, e_{2i-1}\}| \text{ and both } F \text{ and } \{e_1, \ldots, e_{2i-1}\} \text{ are forests of } G, \text{ i.e., independent sets in its cycle matroid.} \]

\[ \text{2.4 Optimal and Greedy Strategies} \]

We define the following strategies:

- An optimal max strategy is a strategy \( \pi^*_{\text{max}} \in \Pi_{\text{max}} \) such that for every strategy \( \pi_{\text{max}} \in \Pi_{\text{max}} \), we have \( \text{val}_{\text{max}}(\pi^*_{\text{max}}) \geq \text{val}_{\text{max}}(\pi_{\text{max}}) \). Such a strategy necessarily exists as the number of max strategies is finite.

- Similarly, \( \pi^*_{\text{min}} \in \Pi_{\text{min}} \) is an optimal min strategy, if for every strategy \( \pi_{\text{min}} \in \Pi_{\text{min}} \), we have \( \text{val}_{\text{min}}(\pi^*_{\text{min}}) \leq \text{val}_{\text{min}}(\pi_{\text{min}}) \).

- A strategy \( g_{\text{max}} \in \Pi_{\text{max}} \) is a greedy strategy for MAX if for every configuration \( F \in F^{\text{even}}_{G} \), it holds that \( g_{\text{max}}(F) \) is a heaviest edge in \( M(F) \). Formally, for every configuration \( F \in F^{\text{even}}_{G} \), we have \( g_{\text{max}}(F) \in \{ e \in M(F) : w(e) = \max \{ w(e') : e' \in M(F) \} \} \).

\[ \text{Remark.} \text{ There may be several optimal and greedy strategies but, from now on, for each weighted graph } G \text{ we define } \pi^*_{\text{min}}, \pi^*_{\text{max}}, \text{ and } g_{\text{max}} \text{ as one of the strategies that satisfy the corresponding conditions and, sometimes, write “the optimal min strategy” or “the greedy max strategy”. Moreover, when evaluating the performance of a greedy strategy,} \]

Also, note that strategies are positional, in the sense they ignore the way in which configurations have been obtained. It is easy to see that memoryfull strategies are not stronger in the spanning-tree game.
we consider the worst case. That is, the value of a greedy strategy is $\min\{val_{\text{max}}(g_{\text{max}}): g_{\text{max}} \text{ is a greedy strategy in } \Pi_{\text{max}}\}$.

2.5 On the Complexity of Evaluating Strategies for MAX

Recall that the maximum spanning-tree problem can be solved in polynomial time. A possible way of computing $\pi_{\text{min}}$ and $\pi_{\text{max}}$ is by solving a Minmax problem, which requires exponential time. We show here that the game setting is indeed more complex than the classical one-player setting. In fact, even evaluating the value of a symbolically given max strategy is co-NP-complete, and the co-NP lower bound holds also for greedy strategies.

Proof. First, if $val_{\text{max}}(\pi_{\text{max}}) \leq k$ then there is a polynomial witness that includes the edges that $\min$ chooses in each turn, such that the weight of the outcome is at most $k$. Hence the membership in co-NP.

We now show the lower bound. Let $G = (V, E)$ be a graph, let $S \subseteq V$, and let $k$ be an integer. The Steiner-tree problem, namely, deciding whether there is a tree in $E$ that spans $S$, is NP-hard. We show a reduction from the Steiner tree problem. We construct a weighted graph $G' = (V', E', w')$ as follows. Let $u_0$ be a vertex in $V$. The set $V'$ is obtained from $V$ by adding $k$ new vertices, namely $V' = V \cup \{u_1, \ldots, u_k\}$. The set $E'$ is obtained from $E$ by adding the edges $\{(u_i, u_{i+1}) : 0 \leq i < k\} \cup (S \times S)$, where parallel edges are allowed. That is, an edge $e \in S \times S$ is added even if it already appears in $E$. For every $e \in E$ we define $w'(e) = 0$, and for every new edge $e \in E' \setminus E$ we define $w'(e) = 1$. Let $\pi_{\text{max}}$ be a max strategy in which max first chooses edges in $\{(u_i, u_{i+1}) : 0 \leq i < k\}$, and when it is not possible anymore she chooses edges in $S \times S$, and when it is not possible anymore she chooses edges in $E$. We prove that there is a tree in $G$ that spans $S$ and has size at most $k$ iff $val_{\text{max}}(\pi_{\text{max}}) \leq k$.

Assume that there is a tree in $G$ that spans $S$ and has size at most $k$. We denote this tree by $T$. Then, while max chooses edges in $\{(u_i, u_{i+1}) : 0 \leq i < k\}$, min can choose all the edges of $T$ and thus ensure that max will not be able to choose edges in $S \times S$ later. Since the edges $\{(u_i, u_{i+1}) : 0 \leq i < k\}$ appear in every spanning tree, the value of $\pi_{\text{max}}$ is $k$.

Assume now that there is no tree in $G$ that spans $S$ and has size at most $k$. Thus, after all the edges in $\{(u_i, u_{i+1}) : 0 \leq i < k\}$ are chosen, there are still edges in $S \times S$ that max can choose, and therefore the value of $\pi_{\text{max}}$ is strictly larger than $k$.

Finally, note that the strategy $\pi_{\text{max}}$ is a worst greedy strategy for max, and hence the problem is co-NP-hard already for this case.

3 The Performance of Optimal and Greedy Strategies w.r.t. the Maximum Spanning Tree

In the game setting, max has a chance to choose only half of the edges in the spanning tree. It is thus not surprising that the outcome of an optimal strategy may be only half of the weight of an MST. Below we formalize this intuition, and show that the half-ratio may be obtained already by a greedy strategy (Theorem 4) and that this upper bound is tight (Theorem 5).
We prove that, in fact, already \( g(x) \) is a factor of \( w \)-by \( w(MST(G)) \).

Proof. Let \( G = (V,E,w) \), and let \( \{e_1, \ldots, e_{n-1}\} \) be a vector of the edges of some maximum spanning tree of \( G \), where \( w(e_i) \geq w(e_{i+1}) \) for every \( 1 \leq i < n - 1 \). Consider the game on \( G \) in which \( \text{MAX} \) plays according to \( g_{\max} \) and \( \text{MIN} \) plays according to some strategy \( \pi_{\min} \).

For every \( 1 \leq j \leq \lfloor (n - 1)/2 \rfloor \), let \( x_j \) denote the edge of \( G \) that \( \text{MAX} \) chooses in her \( j \)-th move. For every \( 1 \leq j \leq \lfloor (n - 1)/2 \rfloor \), let \( y_j \) denote the edge of \( G \) that \( \text{MIN} \) chooses in his \( j \)-th move. Our goal is to prove that

\[
\sum_{j=1}^{\lfloor (n-1)/2 \rfloor} w(x_j) + \sum_{j=1}^{\lfloor (n-1)/2 \rfloor} w(y_j) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j).
\]

We prove that, in fact, already \( \sum_{j=1}^{\lfloor (n-1)/2 \rfloor} w(x_j) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j) \). Since all edge-weights are non-negative, this implies our goal.

To see this, consider an integer \( 0 \leq k < (n - 1)/2 \). Note that \( |\{x_1, \ldots, x_k, y_1, \ldots, y_k\}| = 2k < 2k + 1 = |\{e_1, \ldots, e_{2k+1}\}| \). Since, moreover, \( \{x_1, \ldots, x_k, y_1, \ldots, y_k\} \) and \( \{e_1, \ldots, e_{2k+1}\} \) are independent sets of a matroid (namely, the cycle matroid of \( G \)), there exists some edge \( e \in \{e_1, \ldots, e_{2k+1}\} \cap M(\{x_1, \ldots, x_k, y_1, \ldots, y_k\}) \). Since \( \text{MAX} \) plays according to the greedy strategy, it must be that \( w(x_k+1) \geq w(e) \geq w(e_{2k+1}) \). Hence, \( \sum_{j=1}^{\lfloor (n-1)/2 \rfloor} w(x_j) \geq \sum_{j=0}^{\lfloor (n-1)/2 \rfloor - 1} w(e_{j+1}) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j) \), and the statement follows.

Theorem 5. For every \( n \geq 1 \), there is a weighted graph \( G_n \) such that \( n = \text{val}_\max(\pi^*_\max) = \frac{1}{2} \cdot w(MST(G_n)) \). In fact, for \( G_n \) we also have \( \text{val}_\max(\pi^*_{\max}) = n \).

Proof. See the weighted graphs \( G_1, G_2, \ldots \) in Figure 2. Note that \( MST(G_n) \) includes all the edges with weight 1, and that \( \text{MIN} \) can ensure that all the edges with weight 0 are chosen.

![Figure 2](image2.png)

Figure 2 A sequence of weighted graphs \( G_1, G_2, \ldots \) such that \( G_n \) satisfies \( n = \text{val}_\max(\pi^*_{\max}) = \text{val}_\max(\pi^*_{\max}) = \frac{1}{2} \cdot w(MST(G_n)) \).

4 The Performance of Greedy Strategies w.r.t. Optimal Ones

In this section we study the performance of the greedy max strategy in comparison to the optimal max strategy. We first define formally what it means for two strategies to approximate each other.

4.1 Approximating Strategies

Given a weighted graph \( G = (V,E,w) \), consider two max strategies \( \pi_{\max}, \pi'_{\max} \in \Pi_{\max} \) and a factor \( \alpha \geq 1 \). We say that \( \pi_{\max} \) is an \( \alpha \)-max-approximation of \( \pi'_{\max} \) if

\[
\text{val}_\max(\pi_{\max}) \geq \frac{1}{\alpha} \cdot \text{val}_\max(\pi'_{\max}) \text{.}
\]
That is, intuitively, $\pi'_{\max}$ is at most $\alpha$ times better than $\pi_{\max}$, where, in both cases, we assume that $\min$ follows an optimal $\min$ strategy.

The max competitive ratio of a strategy $\pi_{\max} \in \Pi_{\max}$ is then the smallest factor $\alpha$ such that $\pi_{\max}$ is an $\alpha$-max approximation of $\pi^*_{\max}$. Namely, $\frac{\text{val}_{\max}(\pi_{\max})}{\text{val}_{\max}(\pi^*_{\max})}$.

**Remark.** [Universal Approximation] We could have defined strategy approximations in a different way, by stating that $\pi_{\max}$ is an $\alpha$-max-approximation of $\pi'_{\max}$ if for every strategy $\pi_{\min} \in \Pi_{\min}$, we have that $w(\pi_{\max}, \pi_{\min}) \geq \frac{1}{\alpha} \cdot w(\pi'_{\max}, \pi_{\min})$. We refer to such an approximation as $\alpha$-max universal approximation. Intuitively, while in $\alpha$-max-approximation the performance of the two max strategies is examined with respect to optimal (possibly different from each other) $\min$ strategies, in $\alpha$-max universal approximation the performance is examined with respect to every $\min$ strategy – the same $\min$ strategy against both max strategies. In Appendix B, we show that $\alpha$-max universal approximation is strictly finer than $\alpha$-max approximation. That is, for all $\pi_{\max}, \pi'_{\max} \in \Pi_{\max}$ and $\alpha \geq 1$, if $\pi_{\max}$ is an $\alpha$-max universal approximation of $\pi'_{\max}$, then $\pi_{\max}$ is an $\alpha$-max approximation of $\pi'_{\max}$, yet possibly $\pi_{\max}$ is an $\alpha$-max approximation of $\pi'_{\max}$ but it is not an $\alpha$-max universal approximation of $\pi'_{\max}$. Moreover, working with a max universal approximation, the competitive ratio of the greedy strategy with respect to the optimal strategy is 2, higher than the ratio we prove in Theorem 7, when working with a max approximation.

### 4.2 The Competitive Ratio of Greedy Max Strategies

We turn to study the max competitive ratio of the greedy strategy. For convenience, we assume that the weight function $w$ is normalized so that $\max\{w(e) : e \in E\} = 1$. It is easy to see that such a normalization is always possible and does not change the ratio of the weights of any two spanning trees.

**Theorem 6.** The max competitive ratio of the greedy strategy is 2.

**Proof.** We first prove that $g_{\max}$ is a 2-max approximation. By Theorem 4, we have $2 \cdot \text{val}_{\max}(g_{\max}) \geq w(\text{MST}(G))$. In addition, as no max strategy can perform better than the weight of a maximum spanning tree, we have that $w(\text{MST}(G)) \geq \text{val}_{\max}(\pi_{\max})$ for all $\pi_{\max} \in \Pi_{\max}$. Hence, $\text{val}_{\max}(g_{\max}) \geq \frac{1}{2} \cdot \text{val}_{\max}(\pi_{\max})$ for all $\pi_{\max} \in \Pi_{\max}$, and we are done.

Next, in order to prove that the factor 2 is tight, consider the graph in Figure 3. It is easy to see that while an optimal max strategy would choose first the parallel edge with weight 1, leading to a spanning tree of weight 2, a greedy strategy may choose first the edge on the right, leading to a spanning tree of weight 1.

![Figure 3](image)

$\text{val}_{\max}(g_{\max}) = 1$ whereas $\text{val}_{\max}(\pi^*_{\max}) = 2$.

### 4.3 A Tighter Analysis

While showing tightness in the general case, the lower-bound proof in Theorem 6 is based on a graph with a maximum spanning tree of a very small weight. In this section we show that $g_{\max}$ approximates $\pi^*_{\max}$ better when $w(\text{MST}(G))$ is large.
Theorem 7. Let $G = (V, E, w)$ be a weighted graph, and assume that the weights in $G$ are normalized such that the maximum weight of an edge in $E$ is 1. Then, $g_{\text{max}}$ is a \(1.5 + \frac{1}{w(\text{MST}(G))}\)-max-approximation of $\pi_{\text{max}}^*$.

Proof. We start with a brief description of the main idea of the proof. Let \((e_1, \ldots, e_n)\) be the edges claimed by MAX and MIN in this order when MAX follows a greedy strategy $g_{\text{max}}$ and MIN follows a strategy $\pi_{\text{min}}$ that is optimal against $g_{\text{max}}$. Using the fact that $g_{\text{max}}$ is a greedy strategy, we will show that MIN has a strategy $\pi_{\text{min}}'$ such that, when pitted against an optimal strategy $\pi_{\text{max}}^*$ of MAX (in fact, against any max strategy), it ensures that the weight of the resulting spanning tree is at most \((1.5 + 1/w(\text{MST}(G))) \cdot \sum_{i=1}^{n-1} w(e_i)\). Note that $\pi_{\text{min}}'$ might not be an optimal min strategy, but this only makes the proven result stronger. The heart of the argument is that as long as MAX can claim high (in comparison to what she claimed when she followed $g_{\text{max}}$), weight edges, MIN can claim quite a few low (in comparison to what he claimed when he followed $\pi_{\text{min}}$) weight edges.

We proceed to the formal proof. Let $\pi_{\text{min}} \in \Pi_{\text{min}}$ be a min strategy for which $\text{val}_{\text{max}}(g_{\text{max}}) = w(g_{\text{max}}, \pi_{\text{min}})$. Let \((e_1, \ldots, e_n)\) be a vector of edges of $T(g_{\text{max}}, \pi_{\text{min}})$, where, for every $1 \leq i \leq n - 1$, if $i$ is odd, then $e_i$ is chosen by MAX in her \(((i+1)/2)\)-th move, and if $i$ is even, then $e_i$ is chosen by MIN in his \((i/2)\)-th move. Let $E_{\text{odd}} = \{e_1, e_3, \ldots, e_b\}$, where $b = n - 1 - (n \pmod{2})$, be the edges chosen by MAX, and let $E_{\text{even}} = \{e_2, e_4, \ldots, e_d\}$, where $a = n - 2 + (n \pmod{2})$, be the edges chosen by MIN. Let $d_1 > \ldots > d_h$ be the distinct weights of the edges in $E_{\text{odd}}$, and let $t_1, \ldots, t_h$ be positive integers such that $E_{\text{odd}}$ contains exactly $t_i$ edges of weight $d_i$ for every $1 \leq i \leq k$. Let $t'_0 = 0$ and, for every $1 \leq i \leq k$, let $t'_i = t'_{i-1} + 2t_i$.

Thus, $t'_i = \sum_{j=1}^{i} 2t_j$. Note that, for every $1 \leq i \leq k$, the edges of $E_{\text{odd}}$ whose weight is $d_i$ are \(\{e_{t_{i-1}+1}, e_{t_{i-1}+2}, \ldots, e_{t_i-1}\}\). For example, $w(e_1) = w(e_3) = \ldots = w(e_{2t_1-1}) = d_1$, and $w(e_{2t_1+1}) = w(e_{2t_1+3}) = \ldots = w(e_{2t_1+2t_1-1}) = d_2$. Since the weights in $G$ are normalized so that the maximum weight of an edge in $G$ is 1 and since $g_{\text{max}}$ is greedy, we have that $d_1 = 1$.

We argue that MIN has a strategy $\pi_{\text{min}}'$, with which he can ensure that, by deviating from the greedy strategy $g_{\text{max}}$, MAX does not greatly improve the weight of the tree she builds with him. We define the strategy $\pi_{\text{min}}'$ as follows. Consider a forest $F_m = \{e'_1, e'_2, \ldots, e'_m\} \in \mathcal{F}_{G_{\text{odd}}}$, where $m < \lfloor \frac{n+1}{2} \rfloor$. Let $0 \leq i < k$ be the unique integer for which $\frac{i}{2} \leq m \leq \frac{i+1}{2}$. Then, $\pi_{\text{min}}'(F_m)$ is an arbitrary edge in $M(F_m) \cap \{e_2, e_4, \ldots, e_{2t_1}\}$; by definition, this is a legal move. Moreover, by the independent set exchange property of the cycle matroid of $G$, such an edge exists. For example, if $m < t_1$, then $\pi_{\text{min}}'(F_m)$ is an arbitrary edge of $\{e_2, e_4, \ldots, e_{2t_1}\}$ that was not chosen earlier and does not close a cycle with $F_m$.

Since $\text{val}_{\text{max}}(\pi_{\text{max}}) \leq w(\pi_{\text{max}}, \pi_{\text{min}})$, it suffices to prove that $w(\pi_{\text{max}}, \pi_{\text{min}}) \leq \frac{1.5 + \frac{1}{w(\text{MST}(G))}}{1}$.

For an integer $t$, let $V'_1, \ldots, V'_t$ be the vertex sets of the connected components induced by the forest \(\{e_1, \ldots, e_t\}\). Let $E^t$ denote the set of edges of $G$ that are contained in some connected component of \(\{e_1, \ldots, e_t\}\), that is, \((u, v) \in E^t\) if and only if there exists some $1 \leq i \leq s_t$ such that $u, v \in V'_i$. Note that every forest in $G$ contains at most $\sum_{j=1}^{s_1} (|V'_j| - 1) = t$ edges of $E^t$.

Let $E^t = \{e'_1, \ldots, e'_{n-1}\}$ denote the edge set of $T(\pi_{\text{max}}, \pi_{\text{min}}')$. Note that by the description of the strategy $\pi_{\text{min}}'$, for every $1 \leq i < k$, the forest \(\{e'_1, e'_2, \ldots, e'_{t'/2}\}\) contains at least $\lfloor \frac{t'/2}{2} \rfloor$ edges from $E^{t'/2} \cap E_{\text{even}}$. Since $E^t \cap E^{t'/2}$ contains at most $t'_i$ edges, it follows that $E^t \cap E^{t'/2}$ contains at most $t'_i - \lfloor \frac{t'/2}{2} \rfloor = \lfloor 1.5 \cdot \frac{t'_i}{2} \rfloor$ edges from $E \setminus E_{\text{even}}$. Note that for every edge $e \in E^{t'/2}$, we have that $w(e) \leq d_{i+1}$. Indeed, otherwise MAX would have chosen $e_{i+1}$ such that $w(e_{i+1}) > d_{i+1}$. Hence, $E^t \setminus E_{\text{even}}$ contains at least $1.5 \cdot \frac{t_i}{2} + 0.5$ edges from \(\{e \in E : w(e) > d_{i+1}\}\)
We now show that $E' \setminus E_{\text{even}}$ contains at most $1.5 \cdot \frac{t_i}{2} + 0.5$ edges. Assume first that $n - 1$ is even and thus $t'_k = n - 1$. The forest $\{e'_1, e'_2, \ldots, e'_{t'_i/2}\}$ contains at least $\lceil \frac{t'_i/2}{2} \rceil$ edges from $E_{\text{even}}$. Since $E'$ contains $t'_k$ edges, it follows that $E'$ contains at most $t'_k - \lceil \frac{t'_i/2}{2} \rceil = [1.5 \cdot \frac{t_i}{2}]$ edges from $E \setminus E_{\text{even}}$. Hence, $E' \setminus E_{\text{even}}$ contains at most $1.5 \cdot \frac{t_i}{2} + 0.5$ edges. Now, assume that $n - 1$ is odd and thus $t'_k = n$. Note that $E'$ contains at least $\lceil \frac{t'_i-1}{2} \rceil = \lceil \frac{0.5n-1}{2} \rceil$ edges from $E_{\text{even}}$. Therefore, the size of $E' \setminus E_{\text{even}}$ is at most $n - 1 - \lceil \frac{0.5n-1}{2} \rceil = \lceil \frac{n}{2} - 0.5 \rceil \leq \lceil \frac{t_i}{2} \rceil - 1.5 \cdot \frac{t_i}{2} + 0.5$.

Since for every $1 \leq i < k$ the forest $E' \setminus E_{\text{even}}$ contains at most $1.5 \cdot \frac{t_i}{2} + 0.5$ edges from $\{e \in E : w(e) > d_{i+1}\}$, and since $E' \setminus E_{\text{even}}$ contains at most $1.5 \cdot \frac{t_i}{2} + 0.5$ edges, then the total weight of $E' \setminus E_{\text{even}}$ is at most $d_1(1.5 \cdot \frac{t_1}{2} + 0.5) + \sum_{i=2}^{k} d_i \cdot \lceil (1.5 \cdot \frac{t_i}{2} + 0.5) - (1.5 \cdot \frac{t_{i-1}}{2} + 0.5) \rceil = d_1(1.5t_1 + 0.5) + \sum_{i=2}^{k} d_i \cdot (1.5t_i) = 0.5d_1 + \sum_{i=1}^{k} 1.5t_id_i$.

We are now ready to bound $\frac{w(\pi_{\text{max}}^*, \pi'_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})}$ from above.

\[
\frac{w(\pi_{\text{max}}^*, \pi'_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = \frac{w(E')}{{\text{val}_{\text{max}}(g_{\text{max}})}} = \frac{w(E')}{w(E_{\text{even}}) + \sum_{i=1}^{t_i} t_id_i} \leq \frac{w(E_{\text{even}}) + w(E' \setminus E_{\text{even}})}{w(E_{\text{even}}) + \sum_{i=1}^{t_i} t_id_i} = \frac{w(E_{\text{even}}) + \sum_{i=1}^{t_i} t_id_i}{w(E_{\text{even}}) + \sum_{i=1}^{t_i} t_id_i} + \frac{\sum_{i=1}^{t_i} 0.5t_id_i}{w(E_{\text{even}}) + \sum_{i=1}^{t_i} t_id_i} \leq 1 + \frac{0.5d_1}{\sum_{i=1}^{t_i} t_id_i} \leq 1 + \frac{0.5}{0.5 \cdot w(MST(G))} = 1 + \frac{1}{w(MST(G))}.
\]

The last inequality follows from the fact $\sum_{i=1}^{t_i} t_id_i \geq 0.5 \cdot w(MST(G))$ (see proof of Theorem 4) and $d_1 = 1$.

The following theorem asserts that the approximation ratio given in Theorem 7 is tight.

**Theorem 8.** Let $n \geq 1$ be an odd integer. There exists a weighted graph $G_n$ with $w(MST(G_n)) = 2n$ and with a maximum edge weight of 1, such that $\frac{w(\pi_{\text{max}}^*, \pi'_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = 1.5 + \frac{1}{w(MST(G_n))}$.

**Proof.** We define $G_n = \langle V, E, w \rangle$ as follows. First, let $V = V_1 \cup V_2$, where $V_1 = \{v_0, v_1, \ldots, v_n\}$ and $V_2 = \{u_1, u_2, \ldots, u_n\}$. Note that the vertex $v_0$ appears in both $V_1$ and $V_2$. Then, let $E = E_1 \cup E_2$ where $E_1 = \{(v_i, u_{i+1}) : 0 \leq i \leq n - 1\}$ and $E_2 \subseteq V_2 \times V_2$ is the disjoint union of two spanning trees $T_2$ and $T_2'$ on the vertices of $V_2$. It is not hard to see that such two spanning trees always exist. For $n \leq 2$, one needs parallel edges, as in $G_1$, which appears in Figure 3. For $n \geq 3$, the graph $G_n$ appears in Figure 4, where the edges in $T_1$ are solid, and these in $T_0$ are dashed.

![Figure 4](image-url) The graph $G_n$ with $\frac{w(\pi_{\text{max}}^*, \pi'_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = 1.5 + \frac{1}{w(MST(G_n))}$. 

For every edge \( e \in E_1 \cup T_1 \) we have \( w(e) = 1 \) and for every edge \( e \in T_0 \) we have \( w(e) = 0 \).

The edges in \( E_1 \) must be contained in every spanning tree of \( G_n \). Therefore, if \( m \) edges from \( T_1 \) are chosen during the game for some \( m \leq n \), then the outcome of the game is \( m + n \).

Thus, an optimal strategy \( \pi_{\text{max}}^* \) is to have as many edges from \( T_1 \) as possible. Hence, by Lemma 2 we have \( \text{val}(\pi_{\text{max}}^*) = \lceil \frac{n}{2} \rceil + n \). In the strategy \( g_{\text{max}} \), \( \text{MAX} \) chooses only the \( n \) edges in \( E_1 \), and hence \( \text{val}(g_{\text{max}}) = n \).

Since \( n \) is odd, we have \( \frac{\text{val}(g_{\text{max}})}{\text{val}(\pi_{\text{max}}^*)} = \frac{\frac{n}{2} + n}{\frac{n}{2} + 0.5 + n} = 1.5 + \frac{1}{2n} = 1.5 + \frac{1}{w(MST(G_n))} \).

### 5 A Stochastic Setting

The weighted graphs \( \{G_n : n \in \mathbb{N} \} \) depicted in Figure 2 form an infinite family of games in which \( g_{\text{max}} \) is an optimal strategy for \( \text{MAX} \). In this section we prove that \( g_{\text{max}} \) is not far from being optimal in a very natural and general case.

**Theorem 9.** Consider the weighted graph \( G = \langle V, E, w \rangle \), where \( V = [n], E = \binom{[n]}{2} \), and \( \{w(e) : e \in E\} \) are independent random variables, each having a uniform distribution over \([0,1]\). Then, asymptotically almost surely (a.a.s., for brevity)

\[
\lim_{n \to \infty} \frac{\text{val}(g_{\text{max}})}{\text{val}(\pi_{\text{max}}^*)} = 1.
\]

The main ingredient in our proof of Theorem 9 is the following result, which is an immediate corollary of the main result of [12] (see also [9] and the many references therein).

**Theorem 10.** For \( n \geq 1 \), consider the complete graph with \( n \) vertices \( K_n \), and let \( \{X_e : e \in E(K_n)\} \) be independent random variables, each having a uniform distribution over \([0,1]\). Let \( Y_m \) (respectively, \( Y_M \)) denote the weight of a minimum (respectively, maximum) spanning tree. Then

(a) \( \lim_{n \to \infty} \Pr(Y_m \leq 1.21) = 1 \).

(b) \( \lim_{n \to \infty} \Pr(Y_M \geq n - 2.21) = 1 \).

**Proof of Theorem 9.** It readily follows from Theorem 4 and Part (b) of Theorem 10 that a.a.s. \( \text{val}(g_{\text{max}}) \geq (n - 2.21)/2 \). Let \( T \) be a spanning tree with weight at most 1.21; such a tree exists a.a.s. by Part (a) of Theorem 10. It follows by Lemma 2 that \( \text{MIN} \) has a strategy to ensure that the tree he builds with \( \text{MAX} \) contains at least \( \lceil |T|/2 \rceil = \lceil (n - 1)/2 \rceil \) edges of \( T \). The weight of the tree they build is thus at most \( 1.21 + \lceil (n - 1)/2 \rceil \leq (n + 2.42)/2 \). Hence, a.a.s.

\[
\lim_{n \to \infty} \frac{\text{val}(g_{\text{max}})}{\text{val}(\pi_{\text{max}}^*)} \geq \lim_{n \to \infty} \frac{(n - 2.21)/2}{(n + 2.42)/2} = 1
\]

as claimed. \( \square \)

### 6 A Two-Turn Variant of the Spanning-Tree Game

In this section we study a variant of the game in which the players alternate turns only once. Formally, we have the following. A game is a pair \( (G, k) \), where \( G = \langle V, E, w \rangle \) is a weighted graph with \( n \) vertices and \( 1 \leq k \leq n - 1 \) is an integer. In a game on \( (G, k) \), first \( \text{MAX} \) chooses a forest \( F \subseteq E \) of size \( k \). Then, \( \text{MIN} \) complements \( F \) to a spanning tree of \( G \) by choosing \( n - 1 - k \) edges. \( \text{MAX} \) wants to maximize the weight of the resulting spanning tree and \( \text{MIN} \)
aims to minimize it. Let $g_{\text{max}} \subseteq E$ be a strategy for MAX in which she chooses a forest of size $k$ with a maximum weight, that is, MAX chooses a forest in a greedy manner. Note that while we still use the notation which was introduced in Subsection 2.4 (e.g., $g_{\text{max}}$), the definition of a strategy is different in this setting. A strategy $\pi_{\text{max}}$ of MAX is simply the edge set of some forest of $G$ of size $k$. Similarly, a strategy $\pi_{\text{min}}$ for MIN is a function that, given a forest $F$ of size $k$, returns a forest $F'$ of size $n - 1 - k$ such that $F \cup F'$ is a spanning tree.

**Theorem 11.** Let $(G, k)$ be a game, where $G = (V, E, w)$ and $|V| = n$. Then, $\text{val}_{\text{max}}(g_{\text{max}}) \geq \frac{k}{n-1} \cdot w(MST(G))$.

**Proof.** Let $T = \{e_1, \ldots, e_{n-1}\}$, where $w(e_1) \geq \ldots \geq w(e_{n-1})$, be an MST obtained by complementing $g_{\text{max}}$ in a greedy manner. That is, $g_{\text{max}} = \{e_1, \ldots, e_k\}$. Note that for every $k < i \leq n - 1$ we have $w(e_{i}) \leq w(e_{k})$. Therefore, $w(MST(G)) = w(T) = w(\{e_1, \ldots, e_k\}) + w(\{e_{k+1}, \ldots, e_{n-1}\}) \leq w(g_{\text{max}}) + (n - k - 1) \cdot w(e_{k})$. Since $w(e_{k}) \leq \frac{1}{k} \cdot w(g_{\text{max}})$, we have $w(MST(G)) \leq w(g_{\text{max}}) + (n - k - 1) \cdot \frac{1}{k} \cdot w(g_{\text{max}}) \leq \frac{n-1}{k} \cdot w(g_{\text{max}})$. △

**Theorem 12.** Let $(G, k)$ be a game, where $G = (V, E, w)$ and $|V| = n$. Then, $g_{\text{max}}$ is a 2-max-approximation.

**Proof.** Let $\pi_{\text{min}}$ be a strategy for which $\text{val}_{\text{max}}(g_{\text{max}}) = w(g_{\text{max}}, \pi_{\text{min}})$ and let $T = T(g_{\text{max}}, \pi_{\text{min}})$. Let $\pi_{\text{max}}$ be an optimal strategy for MAX. Consider the strategy $\pi_{\text{min}}$ of MIN in which $\pi_{\text{max}}$ is complemented to a spanning tree as follows. Since $|\pi_{\text{max}}| = k$ and $|T| = n - 1$, MIN can choose $n - 1 - k$ edges from $T$ due to the independent set exchange property of the cycle matroid of $G$. For such a strategy $\pi'_{\text{min}}$, we have $\text{val}_{\text{max}}(\pi'_{\text{max}}, \pi'_{\text{min}}) \leq w(\pi'_{\text{max}}, \pi'_{\text{min}}) \leq w(\pi_{\text{max}}) + w(T)$. Since $g_{\text{max}}$ is a forest of maximum weight among all forests of $G$ with $k$ edges, it follows that $w(\pi_{\text{max}}) \leq w(g_{\text{max}})$, and thus $\text{val}_{\text{max}}(\pi'_{\text{max}}) \leq w(g_{\text{max}}) + w(T) \leq 2 \cdot w(T) = 2 \cdot \text{val}_{\text{max}}(g_{\text{max}})$. △

The following result is a straightforward consequence of Theorems 11 and 12.

**Corollary 13.** Let $(G, k)$ be a game, where $G = (V, E, w)$ and $|V| = n$. Then, $g_{\text{max}}$ is a $\min\{2, \frac{n-1}{k}\}$-max-approximation.

In the following theorem we show that the approximation ratio in Corollary 13 is tight.

**Theorem 14.** Let $n > 1$ and $1 \leq k \leq n - 1$ be integers. There exists a game $(G, k)$, where $G = (V, E, w)$ and $|V| = n$, such that $\frac{\text{val}_{\text{max}}(\pi_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = \min\{2, \frac{n-1}{k}\}$, where $\pi_{\text{max}}$ is an optimal strategy for MAX in $G$.

**Proof.** Let $V = V_1 \cup V_2$, where $V_1 = \{v_0, v_1, \ldots, v_k\}$ and $V_2 = \{v_0, u_1, \ldots, u_{n-1-k}\}$. Note that the vertex $v_0$ appears in both $V_1$ and $V_2$. Let $E = E_1 \cup E_2$, where $E_1 = \{(v_i, v_{i+1}) : 0 \leq i \leq k - 1\}$ and $E_2 = E(T_0) \cup E(T_1)$, where $T_0$ and $T_1$ are edge-disjoint spanning trees of $G[V_2]$ (we allow parallel edges in $E_2$). For every edge $e \in E_1 \cup E_2$ we set $w(e) = 1$ and for every edge $e \in T_0$ we set $w(e) = 0$. Note that if MAX chooses $m$ edges in $T_1$ for some $m \leq n - 1 - k$, then MIN can choose $n - 1 - k - m$ edges in $T_0$ due to the independent set exchange property of the cycle matroid of $G$. The edges of $E_1$ must be contained in every spanning tree of $G$. Therefore, if MAX chooses $m$ edges from $T_1$, then the outcome of the game is $m + k$. Thus, the optimal strategy $\pi_{\text{max}}$ contains as many edges from $T_1$ as possible, namely, $\min\{k, n - 1 - k\}$ edges from $T_1$. The strategy $g_{\text{max}}$ contains the $k$ edges in $E_1$, and therefore $\text{val}_{\text{max}}(g_{\text{max}}) = k$.

If $k \leq \frac{n-1}{2}$ then $\pi_{\text{max}}$ contains $k$ edges from $T_1$ and hence we have $\frac{\text{val}_{\text{max}}(\pi_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = \frac{2k}{k} = 2 = \min\{2, \frac{n-1}{k}\}$. If $k > \frac{n-1}{2}$ then $\pi_{\text{max}}$ contains $n - 1 - k$ edges from $T_1$ and hence we have $\frac{\text{val}_{\text{max}}(\pi_{\text{max}})}{\text{val}_{\text{max}}(g_{\text{max}})} = \frac{n-1}{k} = \min\{2, \frac{n-1}{k}\}$. △
7 Discussion

We studied a game variant of the classic maximum spanning-tree problem. Both the classic problem and our spanning-tree game can be generalized in a straightforward way to all matroids. In the game setting, given a weighted matroid \( M = (E, \mathcal{I}, w) \), \textsc{max} and \textsc{min} alternate turns in claiming elements of \( E \) while ensuring that the set of elements claimed so far by both players is in \( \mathcal{I} \). The game is over as soon as the set of claimed elements is a basis \( B \) of \( M \). \textsc{max} aims to maximize the total weight of \( B \) and \textsc{min} aims to minimize it. It is not hard to show that all of our results (with the exception of Theorem 9, which deals only with weighted complete graphs) apply in this more general setting. The only non-trivial generalization is that of one specific point in the proof of Theorem 7, which we explain below.

When defining \( E^t \), instead of relying on the connected components of the forest \( \{e_1, \ldots, e_t\} \), one can use the rank function\(^5\) \( r \) of the matroid. That is, \( E^t = \{ e \in E : r(\{e\} \cup \{e_1, \ldots, e_t\}) = r(\{e_1, \ldots, e_t\}) \} \). It then readily follows from the definitions of \( r \) and of \( E^t \) that \( |B \cap E^t| \leq t \) holds for every \( B \in \mathcal{I} \).

The graph depicted in Figure 3, which is used to show that, in general, the competitive ratio of greedy strategies is 2, contains parallel edges. One then wonders whether the competitive ratio of greedy strategies is better than 2 under the assumption that the graph on which the game is played is simple. At the moment we only know that this ratio is between 5/3 and 2. One can also consider graphs that are not only simple, but have a large girth\(^6\). The intuition behind this is that, in order to prevent \textsc{max} from claiming a certain edge, \textsc{min} must ensure that claiming it closes a cycle, and this seems harder if all cycles are long. Moreover, when the girth is 2, i.e., there are parallel edges, we know that the competitive ratio is 2. On the other hand, when the game is played on a tree, i.e., the girth is infinite, the competitive ratio is trivially 1. This shows that increasing the girth does decrease (in some way) the competitive ratio of greedy strategies from 2 to 1.

Finally, our game is a special case of the so-called biased game, in which \textsc{max} claims \( p \) edges per turn and then \textsc{min} claims \( q \) edges per turn, where \( p \) and \( q \) are positive\(^7\) integers that are allowed to grow with \( n \). It would be interesting to study how changing the parameters \( p \) and \( q \) would affect our results.

Acknowledgment We thank Yuval Peled for helpful discussions.

\(^5\) The rank function of a matroid \( M = (E, \mathcal{I}) \) is a mapping \( r : 2^E \rightarrow \mathbb{N} \) that maps each subset \( A \) of \( E \) to the size of a largest independent set it contains; i.e., \( r(A) = \max\{|B| : B \subseteq A, B \in \mathcal{I}\} \).

\(^6\) The girth of a graph \( G \) is the length of a shortest cycle in \( G \). If \( G \) is a forest, then its girth is defined to be \( \infty \).

\(^7\) In fact, by allowing \( p = 0 \) (respectively, \( q = 0 \)) we get the original minimum (resp., maximum) spanning tree problem for which greedy strategies are optimal regardless of the value of \( q \) (resp., \( p \)).

A The Competitive Ratio of Min Strategies

In this section we show that, unlike the case of max strategies, one cannot bound the ratio between the outcome of an optimal or a greedy min strategy and the minimum spanning tree. Intuitively, it follows from the fact that the performance of strategies is strongly related to our ability to guarantee a favorable outcome even if we can control only half of the choices. Such a control guarantees that max can add to the spanning tree at least half of the heaviest edges in a maximum spanning tree. Such a control also guarantees that min can add to the spanning tree at least half of the lightest edges in a minimum spanning tree. Without, however, a bound on the ratio between the heaviest and lightest edge, such a guarantee is not of much help. Below we formalize this intuition. We first need some notation, dual to the one defined in Subsection 2.4.

Consider a weighted graph $G = \langle V, E, w \rangle$. A strategy $g_{\min} \in \Pi_{\min}$ is a greedy strategy for $\min$ if for every configuration $F \in \mathcal{F}_G^{\text{odd}}$, it holds that $g_{\min}(F)$ is a lightest edge in $M(F)$. Formally, for every configuration $F \in \mathcal{F}_G^{\text{odd}}$, we have $g_{\min}(F) \in \{e \in M(F) : w(e) = \min\{w(e') : e' \in M(F)\}\}$. Recall that the value of a min strategy is the weight of its outcome against a most maximizing strategy of max. Formally, $val_{\min}(\pi_{\min}) = \max\{w(\pi_{\max}, \pi_{\min}) : \pi_{\max} \in \Pi_{\max}\}$. Then, $\pi^*_{\min}$ is an optimal min strategy, namely one for which $val_{\min}(\pi_{\min})$ is minimal. Finally, let $w(mST(G))$ denote the weight of a minimum spanning tree in $G$.

\textbf{Theorem 15.} It is impossible to bound the ratio between the outcome of an optimal or a greedy min strategy and the minimum spanning tree: For every $\alpha \geq 1$, there is a weighted graph $G_\alpha$ such that $val_{\min}(\pi_{\min}) = val_{\min}(g_{\min}) \geq \alpha \cdot w(mST(G_\alpha))$.

\textbf{Proof.} We define $G_\alpha$ as a triangle with edges of weights 1, $\frac{1}{\alpha}$, and 0. It is easy to see that while $w(mST(G_\alpha)) = \frac{1}{\alpha}$, an optimal strategy for max picks first the edge with weight 1, causing $val_{\min}(\pi_{\min})$ as well as $val_{\min}(g_{\min})$ to be 1. ◀

Note that in the example described in the proof of Theorem 15, the arguments stay valid in a game in which min moves first. As we discuss below, when studying the ratio between greedy and optimal min strategies, the identity of the player that moves first is of great importance: If we dualize the definition of the game given in Section 2, namely let min moves first, then we cannot bound this ratio. If, however, we let max moves first, then we can bound this ratio by 2. Formalizing this involves some more definitions and notations.

For two min strategies $\pi_{\min}, \pi'_{\min} \in \Pi_{\min}$ and a factor $\alpha \geq 1$, we say that $\pi_{\min}$ is an $\alpha$-min-approximation of $\pi'_{\min}$ if $val_{\min}(\pi_{\min}) \leq \alpha \cdot val_{\min}(\pi'_{\min})$. That is, intuitively, $\pi'_{\min}$ is at most $\alpha$ times better than $\pi_{\min}$. Equivalently, when min follows $\pi_{\min}$, the weight of the obtained spanning tree is at most $\alpha$ times the weight of the spanning tree obtained in case he follows $\pi'_{\min}$.

The min competitive ratio of a strategy $\pi_{\min} \in \Pi_{\min}$ is then the smallest factor $\alpha$ such that $\pi_{\min}$ is an $\alpha$-min-approximation of $\pi^*_{\min}$.

\textbf{Theorem 16.} [The min competitive ratio of greedy strategies]

1. It is impossible to bound the min competitive ratio of greedy min strategies in games in which min moves first: for every $\alpha \geq 1$, there is a weighted graph $G_\alpha$ such that $val_{\min}(g_{\min}) \geq \alpha \cdot val_{\min}(\pi_{\min})$.

2. Thus, $val_{\min}(g_{\min}) \leq 2 \cdot val_{\min}(\pi^*_{\min})$. 

Proof. For the first claim, consider the weighted graph $G_\alpha$ appearing in Figure 5. It is easy to see that while an optimal min strategy would choose first the parallel edge with weight $\frac{1}{\alpha}$, leading to a spanning tree of weight $\frac{1}{\alpha}$, a greedy strategy would choose first the edge on the right, leading to a spanning tree of weight 1. Moreover, changing the weight from $\frac{1}{\alpha}$ to 0, the ratio between the two outcomes become $\infty$.

\begin{figure}
\centering
\includegraphics[width=0.2\textwidth]{figure5}
\caption{val$_{\min}(g_{\min}) = 1$ whereas val$_{\max}(\pi_{\min}^*) = \frac{1}{\alpha}$.}
\end{figure}

The second claim follows from the fact that in games in which MAX starts, she can make sure that the weight of the generated tree is at last half of the weight of the maximum spanning tree. Hence, the ratio between any two min strategies cannot be larger than 2.

Formally, we have the following. Recall that, by Theorem 4, for every weighted graph $G$, we have that \(\text{val}_{\max}(\pi_{\max}) \geq \frac{1}{2} \cdot w(\text{MST}(G))\). Hence, for every strategy $\pi_{\min} \in \Pi_{\min}$, in particular for $\pi_{\min}^*$, we have that $\text{val}_{\min}(\pi_{\min}) \geq \frac{1}{2} \cdot w(\text{MST}(G))$. In addition, clearly $\text{val}_{\min}(g_{\min}) \leq w(\text{MST}(G))$. Hence, $\text{val}_{\min}(g_{\min}) \leq 2 \cdot \text{val}_{\min}(\pi_{\min}^*)$, and we are done. □

B. $\alpha$-max Universal Approximation

In this section we prove that $\alpha$-max universal approximation is strictly finer than $\alpha$-max approximation. Moreover, we prove that, with respect to this finer definition, the upper bound of 2 on the competitive ratio that follows from Theorem 4 cannot be improved. This is in contrast to the assertion of Theorem 7, which applies to our usual definition of approximation for max strategies.

\begin{theorem}
$\alpha$-max universal approximation is strictly finer than $\alpha$-max approximation.
\end{theorem}

That is, for all $\pi_{\max}, \pi'_{\max} \in \Pi_{\max}$ and $\alpha \geq 1$, if $\pi_{\max}$ is an $\alpha$-max universal approximation of $\pi'_{\max}$, then $\pi_{\max}$ is an $\alpha$-max approximation of $\pi'_{\max}$; yet possibly $\pi_{\max}$ is an $\alpha$-max approximation of $\pi_{\max}'$ but it is not an $\alpha$-max universal approximation of $\pi_{\max}'$.

Proof. Assume that $\pi_{\max}$ is an $\alpha$-max universal approximation of $\pi'_{\max}$, and let $\hat{\pi}_{\min}$ be a min strategy for which $\text{val}_{\max}(\pi_{\max}) = w(\pi_{\max}, \hat{\pi}_{\min})$. By the definition of $\alpha$-max universal approximation, we have that $w(\pi_{\max}, \hat{\pi}_{\min}) \geq \frac{1}{\alpha} \cdot w(\pi'_{\max}, \hat{\pi}_{\min})$. By the evaluation of max strategies, we have $w(\pi'_{\max}, \hat{\pi}_{\min}) \geq \text{val}_{\max}(\pi'_{\max})$. Hence, $\text{val}_{\max}(\pi_{\max}) \geq \frac{1}{\alpha} \cdot \text{val}_{\max}(\pi'_{\max})$. Thus $\pi_{\max}$ is an $\alpha$-max approximation of $\pi'_{\max}$.

In order to prove that $\alpha$-max-universal-approximation is strictly finer, i.e., to prove that there are strategies $\pi_{\max}$ and $\pi'_{\max}$ such that $\pi_{\max}$ is an $\alpha$-max approximation of $\pi'_{\max}$ but it is not an $\alpha$-max universal approximation of $\pi'_{\max}$, one can use Theorem 7 and the weighted graphs $G_n$ defined in Theorem 18 below. Indeed, it follows by Theorem 18 that, for sufficiently large $n$, the strategy $g_{\max}$ is not a 1.75-max universal approximation of $\pi_{\max}^*$. On the other hand, by Theorem 7, $g_{\max}$ is a 1.75-max approximation of $\pi_{\max}^*$.

We now show that, when working with max-universal approximation, the assertion of Theorem 4 is asymptotically tight, already when comparing greedy strategies to optimal ones.

\begin{theorem}
For every non-negative integer $n$, there is a weighted graph $G_n$ such that there exists a min strategy $\pi_{\min}$ for which $w(g_{\max}, \pi_{\min}) = n+1$ and $w(\pi_{\max}^*, \pi_{\min}) = 2n+1$.
\end{theorem}
Proof. Fix a non-negative integer $n$ and define $G_n$ as follows. Its vertex set is $V = \{u, v_0, v_1, \ldots, v_{2n}\}$. Its edge set is $E = \{e\} \cup E'$, where $e = \langle u, v_0 \rangle$ and $E'$ is the edge-disjoint union of two spanning trees $T_0$ and $T_1$ on the vertices $\{v_0, v_1, \ldots, v_{2n}\}$. Finally, the weight of every edge of $T_0$ is 0 and the weight of any other edge in $E$ is 1.

Next, we define the strategy $\pi_{\min}$. For every forest $F \subseteq E$, if $e \in F$, then $\pi_{\min}(F)$ is some edge of $T_0 \setminus M(F)$, otherwise $\pi_{\min}(F)$ is some edge of $T_1 \setminus M(F)$.

Now, when playing according to $\pi^{\ast}_{\max}$, $\max$ claims only edges of $T_1$ as long as this is possible. By the definition of $\pi_{\min}$, $\min$ claims edges of $T_1$ as well. Hence $T(\pi^{\ast}_{\max}, \pi_{\min}) = T_1 \cup \{e\}$, and thus $w(\pi^{\ast}_{\max}, \pi_{\min}) = 2n + 1$. On the other hand, a worst greedy strategy $g_{\max}$ instructs $\max$ to claim $e$ in her first move. By the definition of $\pi_{\min}$ and by Lemma 2, the outcome $T(g_{\max}, \pi_{\min})$ contains exactly half of the edges of $T_1$. Since every spanning tree of $G_n$ contains $e$, we conclude that $w(g_{\max}, \pi_{\min}) = n + 1$.

Combining Theorems 18 and 4 implies the following result.

**Corollary 19.** The competitive ratio of greedy strategies with respect to max-universal approximation tends to 2 as the weight of an MST tends to infinity.
